To so many fine memories of my mother Ashraf, my father
Mohammad, and my brother Mohsen, for their uncompromising
belief in the power of education.

About the Editor-in-Chief

Hossein Bidgoli, Ph.D., is professor of Management Information Systems at California State University. Dr. Bidgoli helped set up the first PC lab in the United States. He is the author of 43 textbooks, 27 manuals, and over five dozen technical articles and papers on various aspects of computer applications, information systems and network security, e-commerce, and decision support systems published and presented throughout the world. Dr. Bidgoli also serves as the editor-in-chief of *The Internet*

Encyclopedia, *The Handbook of Information Security*, and *The Encyclopedia of Information Systems*.

The Encyclopedia of Information Systems was the recipient of one of the Library Journal's Best Reference Sources for 2002 and *The Internet Encyclopedia* was recipient of one of the PSP Awards (Professional and Scholarly Publishing), 2004. Dr. Bidgoli was selected as the California State University, Bakersfield's 2001–2002 Professor of the Year.

Contents

Contributors	xvii	Video Compression	227
Preface	xxiii	<i>Immanuel Freedman</i>	
Guide to The Handbook of Computer Networks	xxvi	Speech and Audio Compression	268
Reviewers List	1055	<i>Peter Kroon</i>	
Index	1065	Multimedia Streaming	282
		<i>Nabil J. Sarhan</i>	
		High-Definition Television	293
		<i>Jim Krause</i>	
Volume I: Key Concepts, Data Transmission, and Digital and Optical Networks			
Part 1: Key Concepts		Part 2: Hardware, Media, and Data Transmission	
The Telecommunications Industry	3	Modems	309
<i>David G. Loomis</i>		<i>Darren B. Nicholson and Jennifer A. Nicholson</i>	
Data Communications Basics	19	Conducted Communications Media	320
<i>Hossein Bidgoli</i>		<i>Thomas L. Pigg</i>	
Data-Link Layer Protocols	30	Wireless Channels	334
<i>Stefan Joe-Yen and Chadwick Sessions</i>		<i>Okechukwu C. Ugweje</i>	
Network Layer Protocols	40	Sources of Errors, Prevention, Detection, and Correction	352
<i>Muhannad Harrim, Mohamed El-Wakil, and Ala Al-Fuqaha</i>		<i>Syed H. Murshid and Azhar M. Khayrattee</i>	
Transport Layer Protocols	63	Routers	364
<i>Vassilis Tsaoussidis</i>		<i>Min Song</i>	
Session, Presentation, and Application Layer Protocols	76	Switches	375
<i>Chadwick Sessions</i>		<i>Min Song</i>	
Digital Transmission	84	Bridges	390
<i>Marvi Teixeira and Viktor Zaharov</i>		<i>Zartash Afzal Uzmi and Tariq Mahmood Jadoon</i>	
Analog Transmission	102	Pulse Amplitude Modulation	403
<i>Hamidreza Saligheh, Joonhyuk Kang, Jaehak Chung, and Vahid Tarokh</i>		<i>Muneo Fukaishi</i>	
Voice Communications Systems: KTS, PBX, Centrex, and ACD	115	Frequency and Phase Modulation	414
<i>Hassan Ibrahim</i>		<i>Albert Lozano-Nieto</i>	
Messaging Systems: Facsimile and Voice Processing	127	Carrierless Amplitude Phase Modulation	426
<i>Albert K.S. Wong, Nan Zhang, and Xu Yan</i>		<i>Tim Collins</i>	
Public Switched Telephone Network	158	Minimum Shift Keying	438
<i>Jingxuan Liu and Nirwan Ansari</i>		<i>Tao Jiang</i>	
Information Theory	178	Optical Differential Phase Shift Keying	455
<i>David Blockus and Mark Stamp</i>		<i>Xiang Liu</i>	
Data Compression	199	DMT Modulation	473
<i>Chang-Su Kim and C.C. Jay Kuo</i>		<i>Stephan Pfletschinger</i>	
Image Compression	212	Pulse Position Modulation	492
<i>Alfred Mertins</i>		<i>Jon Hamkins</i>	

Digital Phase Modulation and Demodulation	509	Fiber-Optic Filters and Multiplexers	850
<i>Zartash Afzal Uzmi</i>		<i>Hamid Hemmati</i>	
Line Coding	522	Optical Solitons	861
<i>Asim Loan</i>		<i>Natalia M. Litchinitser</i>	
Spread Spectrum	538	Synchronous Optical Code Division Multiplexing Systems	885
<i>Murad Hizlan</i>		<i>Hideyuki Sotobayashi</i>	
Frequency Division Multiplexing	553	Free-Space Optics	900
<i>Zhu Liu</i>		<i>John Liu and Mark Schaefer</i>	
Time Division Multiplexing	568	Optical Switching Techniques in WDM Optical Networks	909
<i>William A. Shay</i>		<i>Amor Lazzez, Nouredine Boudriga, and Mohammad S. Obaidat</i>	
Statistical Time Division Multiplexing	579	SONET and SDH Networks	929
<i>Kavitha Chandra</i>		<i>M. Farooque Mesiya</i>	
Orthogonal Frequency Division Multiplexing	591	Passive Optical Networks for Broadband Access	948
<i>Shinsuke Hara</i>		<i>Nirwan Ansari and Yuanqiu Luo</i>	
Wavelength Division Multiplexing	606		
<i>Yassine Khelifi, Nouredine Boudriga, and Mohammad S. Obaidat</i>			
 Part 3: Digital and Optical Networks		 Volume II: LANs, MANs, WANs, The Internet, and Global, Cellular, and Wireless Networks	
Digital Communication Basics	629	Part 1: LANs, MANs, and WANs	
<i>Robert W. Heath and Atul A. Salvekar</i>		Local Area Networks	3
Digital Radio Broadcasting	642	<i>Wayne C. Summers</i>	
<i>Zhuojun Joyce Chen</i>		Ethernet LANs	19
Spread Spectrum Signals for Digital Communications	675	<i>William Stallings</i>	
<i>Filippo Giannetti and Marco Luise</i>		Token Ring LANs	27
Optical Fiber Communications	692	<i>Norman C. Strole, Werner Bux, and Robert D. Love</i>	
<i>Habib Hamam and Sghaier Guizani</i>		Optical Fiber LANs	40
Optical Transmitters, Receivers, and Noise	708	<i>Mo Adda, Amanda Peart, and Jau Ming Chew</i>	
<i>Ken Pedrotti</i>		Windows 2000 Operating System	57
Optical Signal Regeneration	729	<i>Dario Forte</i>	
<i>Mingshan Zhao</i>		Linux Operating System	78
Optical Sources	745	<i>Mark Shacklette</i>	
<i>Tin Win and Serge Demidenko</i>		Metropolitan Area Networks	91
Lambda and Sub-Lambda Switching	767	<i>Richard J. Nieporent</i>	
<i>Mario Baldi and Yoram Ofek</i>		Terrestrial Wide Area Networks	116
Optical Cross Connects	783	<i>Gurdeep Singh Hura</i>	
<i>Wen-De Zhong</i>		Packet Switching	136
Optical Memories	795	<i>Qinqing Zhang and Qi Bi</i>	
<i>Paul W. Nutter</i>		Circuit Switching	146
Characterization of Optical Fibers	815	<i>Farid Farahmand and Qiong (Jo) Zhang</i>	
<i>Liang Chen, John Cameron, and Xiaoyi Bao</i>			
Optical Couplers and Splitters	828		
<i>Kais Dridi, Mustapha Razzak, and Habib Hamam</i>			

Message Switching	159	Voice Over Internet Protocol	468
<i>Farid Farahmand</i>		<i>Sherali Zeadally and Farhan Siddiqui</i>	
Frame Relay	172	Signaling Approaches	488
<i>Eddie Rabinovitch</i>		<i>Edmundo Monteiro, Fernando Boavida, Marilia Curado, and Luís Cordeiro</i>	
Asynchronous Transfer Mode (ATM)	183	Voice over MPLS and VoIP over MPLS	509
<i>Arjan Durresi and Raj Jain</i>		<i>Junaid Ahmed Zubairi</i>	
Broadband Integrated Services Digital Network	200	Telephone Number Mapping (ENUM)	519
<i>B. Muthukumaran</i>		<i>Leslie L. Daigle</i>	
DSL (Digital Subscriber Line)	210	Web Hosting	532
<i>Milos Milosevic</i>		<i>Thomas C. Bressoud</i>	
Cable Modems	221	End-System QoS	545
<i>Shaheed N. Mohammed</i>		<i>Tarek F. Abdelzhaer and Chengdu Huang</i>	
Home Networking	230	Web Services	559
<i>Sherali Zeadally</i>		<i>Mei-Ling L. Liu</i>	
Multimedia Networking	246		
<i>Hans-Peter Dommel</i>			
 Part 2: The Internet, Global Networks, and VoIP			
The Internet Fundamentals	267	Cellular Communications Channels	579
<i>Hossein Bidgoli</i>		<i>Aarne Mämmelä and Risto Wichman</i>	
History of the Internet	280	Cellular Telephony	591
<i>John Lucas Sherry and Nicholas David Bowman</i>		<i>Elyes Ben Ali Bdira</i>	
Internet2®	294	Mobile Radio Communications	616
<i>Linda Bruenjes and Carolyn Siccama</i>		<i>Chi Zhou</i>	
Internet Domain Name System	305	Evolution of Mobile Cellular Networks	630
<i>Krishna Jayakar</i>		<i>Jiang Xie and Xiaoyuan Gu</i>	
Information Retrieval on the Internet	320	Global System for Mobile Communications	642
<i>Raymond F. Wisman</i>		<i>Mohamed A. Haleem and Koduvayur P. Subbalakshmi</i>	
Internet Architecture	345	General Packet Radio Service	658
<i>Geoffrey G. Xie</i>		<i>Allen H. Levesque</i>	
TCP/IP Suite	358	Location Management in Personal Communication Systems	675
<i>Prabhaker Mateti</i>		<i>Jingyuan Zhang and Ivan Stojmenovic</i>	
SMTP (Simple Mail Transfer Protocol)	388	Mobility Management in Heterogeneous Networks	685
<i>Vladimir V. Riabov</i>		<i>Guangbin Fan, Xuming Lu, and Song Ci</i>	
IP Multicast	407	Universal Mobile Telecommunications System	699
<i>Emilia Rosti</i>		<i>Faouzi Zarai, Noureddine Boudriga, and Mohammad S. Obaidat</i>	
Network QoS	417	International Mobile Telecommunications-2000 and 3G Wireless Systems	716
<i>Ying Lu</i>		<i>Mustafa M. Matalgah and Omar M. Hammouri</i>	
Internet Security Standards	428	Code Division Multiple Access (CDMA)	751
<i>Raymond R. Panko</i>		<i>Frank H.P. Fitzek and Marcos Katz</i>	
Technology and Standards for Low-Bit-Rate Vocoding Methods	447		
<i>Miguel Arjona Ramírez and Mário Minami</i>			

Time-Division Multiple Access	769	Data Monitoring and Gathering in Sensor Networks	1113
<i>Tom S. Chan</i>		<i>Symeon Papavassiliou, Stella Kafetzoglou, and Jin Zhu</i>	
Carrier Sense Multiple Access Protocols	779	In-Network Data Aggregation in Wireless Sensor Networks	1131
<i>Wei Ye</i>		<i>Kemal Akkaya and Ismail Ari</i>	
Bluetooth Technology	790	Cognitive and Software Defined Radios for Dynamic Spectrum Access	1147
<i>Brent A. Miller</i>		<i>Troy Weingart and Douglas C. Sicker</i>	
Satellite Communications Basics	802	Localization in Wireless Networks	1158
<i>Michele Luglio and Antonio Saitto</i>		<i>Slim Rekhis, Noureddine Boudriga, and Mohammad S. Obaidat</i>	
Land-Mobile Satellite Channel	815	Interference Management in Wireless Networks	1178
<i>Emilio Matricciani</i>		<i>Keivan Navaie and Shahrokh Valaee</i>	
Geosynchronous Fixed Satellite Communications	836	Wireless Wide Area Networks	1191
<i>Michele Luglio and Antonio Saitto</i>		<i>Anthony H. Smith and Raymond A. Hansen</i>	
Satellites in IP Networks	860	Wireless Broadband Access	1200
<i>Fatih Alagöz and Abbas Jamalipour</i>		<i>Hsiao-Hwa Chen and Mohsen Guizani</i>	
Global Navigation Satellite Systems	877	Indoor Wireless Infrared Communications	1223
<i>Omar Al-Bayari and Balqies Sadoun</i>		<i>Z. Ghassemlooy</i>	
Wireless LANs	896		
<i>Mohammad S. Obaidat, G. I. Papadimitriou, and S. Obaidat</i>			
Wireless LAN Standards	917		
<i>Prashant Krishnamurthy</i>			
Bit-Interleaved Coded Modulation	935		
<i>Yuheng Huang and James A. Ritcey</i>			
The Wireless Application Protocol	955		
<i>Lillian N. Cassel and Arun Srinivasa Murthy</i>			
Wireless ATM	972		
<i>Amel Meddeb and Noureddine Boudriga</i>			
Wireless IP Telephony	991		
<i>Manish Marwah and Shivakant Mishra</i>			
Wireless Internet	1000		
<i>Abbas Jamalipour</i>			
Internetworking of Heterogeneous Wireless Networks	1018		
<i>Sherali Zeadally and Farhan Siddiqui</i>			
Principles and Applications of Ad Hoc and Sensor Networks	1040		
<i>Marco Conti</i>			
Medium Access in Ad Hoc and Sensor Networks	1057		
<i>Vojislav B. Mišić and Jelena Mišić</i>			
Emerging Trends in Routing Protocols in Mobile Wireless Ad Hoc and Sensor Networks	1084		
<i>Jamal N. Al-Karaki</i>			
Broadcasting in Ad Hoc and Sensor Networks	1101		
<i>François Ingelrest, David Simplot-Ryl, Hong Guo, and Ivan Stojmenović</i>			
		Volume III: Distributed Networks, Network Planning, Control, Management, and New Trends and Applications	
		Part 1: Distributed Networks	
		Client/Server Computing Basics	3
		<i>Daniel McFarland and Darren B. Nicholson</i>	
		Groupware	16
		<i>Robert Slagter</i>	
		Network Middleware	33
		<i>Linda Volonino and Pragati Dalal</i>	
		Grid Computing Fundamentals	45
		<i>Mark Baker</i>	
		Grid Computing Implementation	63
		<i>Barry Wilkinson and Clayton Ferner</i>	
		Cluster Computing Fundamentals	79
		<i>Hong Ong and Mark Baker</i>	
		Next-Generation Cluster Networks	93
		<i>Keren Bergman, Benjamin A. Small, and Larry A. Bergman</i>	
		Utility Computing on Global Grids	110
		<i>Chee Shin Yeo, Rajkumar Buyya, Marcos Dias de Assunção, Jia Yu, Anthony Sulistio, Srikumar Venugopal, and Martin Placek</i>	

Peer-to-Peer Network Architecture	131	Computer Viruses and Worms	440
<i>Jing Wu and Michel Savoie</i>		<i>Robert Slade</i>	
Peer-to-Peer Network Applications	152	Denial of Service Attacks	454
<i>Stan Kurkovsky</i>		<i>Qijun Gu and Peng Liu</i>	
Incentive Issues in Peer-to-Peer Systems	168	E-Mail Threats and Vulnerabilities	469
<i>Yu-Kwong Kwok</i>		<i>David Harley</i>	
Storage Area Network Fundamentals	189	Virtual Private Networks	488
<i>Vladimir V. Riabov</i>		<i>G. I. Papadimitriou, M. S. Obaidat, C. Papazoglou, and A.S.Pomportsis</i>	
Fiber Channel	205	Cryptography	505
<i>Jiying Zhao</i>		<i>Ari Juels</i>	
Storage Area Networks: Architectures and Protocols	217	Access Control	518
<i>Nirwan Ansari and Si Yin</i>		<i>Sabrina De Capitani di Vimercati, Sara Foresti, Stefano Paraboschi, and Pierangela Samarati</i>	
Distributed Intelligent Networks	235	Biometrics	539
<i>G. N. Prezerakos and I. S. Venieris</i>		<i>James L. Wayman</i>	
Smart Cards: Communication Protocols and Applications	251	Firewalls	553
<i>Michael Tunstall, Konstantinos Markantonakis, Damien Sauveron, and Keith Mayes</i>		<i>James E. Goldman</i>	
Fault-Tolerant Systems	269	Authentication	570
<i>Amiya Nayak</i>		<i>Patrick McDaniel</i>	
Distributed Algorithms	286	Password Authentication	581
<i>Valmir C. Barbosa</i>		<i>Jeremy L. Rasmussen</i>	
Distributed Databases	298	Physical Security Threats and Measures	596
<i>David Coquil and Harald Kosch</i>		<i>Mark Michael</i>	
Part 2: Network Planning, Control, and Management		Computer Security Incident Response Teams (CSIRTs)	632
Network Capacity Planning	315	<i>Raymond R. Panko</i>	
<i>Priscilla Oppenheimer</i>		Backup and Recovery System Requirements	639
Network Traffic Modeling	326	<i>David R. Reavis</i>	
<i>Thomas M. Chen</i>		Business Requirements of Backup Systems	650
Network Traffic Management	340	<i>Markus Klemen, Thomas Neubauer, and Edgar R. Weippl</i>	
<i>Thomas M. Chen</i>		Evaluating Storage Media Requirements	662
Network Security Risk Assessment and Management	354	<i>David R. Reavis</i>	
<i>Dan Port, Rick Kazman, and David Klappholz</i>		Business Continuity Planning	671
Network Reliability and Fault Tolerance	372	<i>Marco Cremonini and Pierangela Samarati</i>

Preface

The Handbook of Computer Networks is the first comprehensive examination of the core topics in the computer network field. *The Handbook of Computer Networks*, a 3-volume reference work, with 202 chapters, 3400+ pages, is a comprehensive coverage of the computer network field with coverage of the core topics.

The primary audience is the libraries of 2-year and 4-year colleges and universities with Computer Science, Computer Engineering, Network Engineering, Telecommunications, Data Communications, MIS, CIS, IT, IS, Data Processing, and Business departments, public and private libraries and corporate libraries throughout the world, and educators and practitioners in the networking and telecommunications fields.

The secondary audience is a variety of professionals and a diverse group of academic and professional courses for the individual volumes.

Among industries expected to become increasingly dependent upon the computer networks and telecommunications and active in understanding the many issues surrounding this important and fast-growing field are: government agencies, military, education, libraries, health, medical, law enforcement, accounting firms, law firms, justice, manufacturing, financial services, insurance, communications, transportation, aerospace, energy, biotechnology, retail, and utilities.

Each volume incorporates state-of-the-art core information and computer networks and telecommunications topics, practical applications, and coverage of the emerging issues in the computer networks field.

This definitive 3-volume *Handbook* offers coverage of both established and cutting-edge theories and developments in the computer networks and telecommunications fields. The *Handbook* contains chapters from global experts in academia and industry. The *Handbook* offers the following unique features:

1. Each chapter follows a unique format including Title and Author, Outline, Introduction, Body, Conclusion, Glossary, Cross-References, and References. This unique format assists the readers to pick and choose various sections of a chapter. It also creates consistency throughout the entire series.
2. The *Handbook* has been written by more than 270 experts and reviewed by more than 1000 academics and practitioners chosen from around the world. These diverse collections of expertise have created the most definitive coverage of established and cutting-edge theories and applications of this fast-growing field.
3. Each chapter has been rigorously peer reviewed. This review process assures the accuracy and completeness of each topic.
4. Each chapter provides extensive online and off-line references for additional reading. This will enable the readers to go further with their understanding of a given topic.
5. More than 1000 illustrations and tables throughout the series highlight complex topics and assist further understanding.
6. Each chapter provides extensive cross-references. This helps the readers to read other chapters related to a particular topic, providing a one-stop knowledge base for a given topic.
7. More than 2500 glossary items define new terms and buzzwords throughout the series, assisting in understanding of concepts and applications.
8. The *Handbook* includes a complete table of contents and index sections for easy access to various parts of the series.
9. The series emphasizes both technical as well as managerial issues. This approach provides researchers, educators, students, and practitioners with a balanced understanding and the necessary background to deal with problems related to understanding computer networks and telecommunications issues and to be able to design a sound computer and telecommunications system.
10. The series has been developed based on the current core course materials in several leading universities around the world and current practices in leading computer, telecommunications, and networking corporations. This format should appeal to a diverse group of educators and researchers in the networking and telecommunications fields.

We chose to concentrate on fields and supporting technologies that have widespread applications in academic and business worlds. To develop this *Handbook*, we carefully reviewed current academic research in the networking field in leading universities and research institutions around the world.

Computer networks and telecommunications, network security, management information systems, network design and management, computer information systems (CIS), and electronic commerce curriculums, recommended by the Association of Information Technology Professionals (AITP) and the Association for Computing Management (ACM) were carefully investigated. We also researched the current practices in the networking field carried out by leading networking and telecommunications corporations. Our work assisted us in defining the boundaries and contents of this project. Its chapters address technical as well as managerial issues in the networking and telecommunications fields.

TOPIC CATEGORIES

Based on our research, we identified nine major topic areas for the Handbook:

- Key Concepts
- Hardware, Media, and Data Transmission
- Digital and Optical Networks
- LANs, MANs, and WANs
- The Internet, Global Networks, and VoIP
- Cellular and Wireless Networks
- Distributed Networks
- Network Planning, Control, and Management
- Computer Network Popular Applications and Future Directions

Although these nine categories are interrelated, each addresses one major dimension of the computer networks and telecommunications fields. The chapters in each category are also interrelated and complementary, enabling readers to compare, contrast, and draw conclusions that might not otherwise be possible.

Though the entries have been arranged logically, the light they shed knows no bounds. The *Handbook* provides unmatched coverage of fundamental topics and issues for successful design and implementation of a computer network and telecommunications systems. Its chapters can serve as material for a wide spectrum of courses such as:

- Grid Computing
- Distributed Intelligent Networks
- Multimedia Networking
- Peer-to-Peer Networks
- Cluster Computing
- Voice over IP
- Storage Area Networks
- Network Backup and Recovery Systems
- Digital Networks
- Optical Networks
- Cellular Networks
- Wireless Networks
- Telecommunications Systems
- Computer Network Management

Successful design and implementation of a sound computer network and telecommunications systems requires a thorough knowledge of several technologies, theories, and supporting disciplines. Networking researchers and practitioners have had to consult many resources to find answers. Some of these sources concentrate on technologies and infrastructures, some on applications and implementation issues, and some on managerial concerns. This *Handbook* provides all of this relevant information in a comprehensive three-volume set with a lively format.

Each volume incorporates core networking and telecommunications topics, practical applications, and coverage of the emerging issues in the networking and telecommunications fields. Written by scholars and practitioners from around the world, the chapters fall into nine major subject areas:

Key Concepts

Chapters in this group examine a broad range of topics. Fundamental theories, concepts, technologies, and applications related to computer networks, data communications, and telecommunications are discussed. These chapters explain the OSI reference model and then discuss various types of compression techniques including data, image, video, speech, and audio compression. This part concludes with a discussion of multimedia streaming and high definition television (HDTV) as their applications are on the rise. The chapters in this part provide a solid foundation for the rest of the Handbook.

Hardware, Media, and Data Transmission

Chapters in this group concentrate on the important types of hardware used in network and telecommunications environments and then examine popular media used in data communications including wired and wireless media. The chapters in this part explain different types of modulation techniques for both digital and optical networks and conclude with coverage of various types of multiplexing techniques that are being used to improve the efficiency and effectiveness of communications media.

Digital and Optical Networks

Chapters in this group discuss important digital and optical technologies that are being used in modern communication and computer networks. Different optical switching techniques, optical devices, optical memories, SONET, and SDH networks are explained.

LANs, MANs, and WANs

This group of chapters examines major types of computer networks including local, metropolitan, and wide area networks. Popular types of operating systems used in a LAN environment are discussed, including Windows and Linux. The chapters also examine various types of switching techniques including packet, circuit, and message switching. The chapters discuss broadband network applications and technologies and conclude with a discussion of multimedia networking.

The Internet, Global Networks, and VoIP

Chapters in this group explore a broad range of topics. They review the Internet fundamentals, history, domain name systems, and Internet2. The architecture and functions of the Internet and important protocols including TCP/IP, SMTP, and IP multicast are discussed. The chapters in this group also explain the network and end-system quality of service and then discuss VoIP and its various components, protocols, and applications.

Cellular and Wireless Networks

Chapters in this group explain cellular and wireless networks. Major standards, protocols, and applications in the cellular environment are discussed. This includes a detailed coverage of GSM, GPRS, UMTS, CDMA, and TDMA. The chapters in this group explore satellite communications

principles, technologies, protocols, and applications in detail. The chapters conclude with coverage of wireless wide area networks and wireless broadband access.

Distributed Networks

The chapters in this group investigate distributed networks, their fundamentals, architectures, and applications. Grid computing, cluster computing, and peer-to-peer networks are discussed in detail. These chapters also explore storage area networks, fiber channels, and fault tolerant systems. This part concludes with a discussion of distributed algorithms and distributed databases.

Network Planning, Control, and Management

The chapters in this group discuss theories, methodologies, and technologies that enhance successful network planning, control, and management. After discussion of network capacity planning and network modeling, the chapters concentrate on the identification of threats and vulnerabilities in a network environment. The chapters then present a number of tools and technologies that if properly utilized could significantly improve the integrity of data resources and computer networks by keeping hackers and crackers at bay. This part concludes with a discussion of business continuity planning, e-mail, and Internet use policies, and computer network management.

Computer Network Popular Applications and Future Directions

Chapters in this group present several popular applications of computer networks and telecommunications systems. These applications could not have been successfully utilized without a sound computer network and telecommunications system. Some of these applications include conferencing, banking, electronic commerce, travel and tourism, and Web-based training and education. This part concludes with a discussion of future trends in computer networking including biologically inspired networking, active networks, and molecular communication.

Specialists have written the *Handbook* for experienced and not so experienced readers. It is to these contributors that I am especially grateful. This remarkable collection of scholars and practitioners have distilled their knowledge

into a fascinating and enlightening one-stop knowledge base in computer networks and telecommunications that “talks” to readers. This has been a massive effort, but one of the most rewarding experiences I have ever had. So many people have played a role that it is difficult to know where to begin.

I should like to thank the members of the editorial board for participating in the project and for their expert advice on help with the selection of topics, recommendations for authors, and reviewing the materials. Many thanks to more than 1000 reviewers who devoted their time by providing advice to me and the authors for improving the coverage, accuracy, and comprehensiveness of these materials.

I thank my senior editor Matt Holt, who initiated the idea of the *Handbook*. Through a dozen drafts and many reviews, the project got off the ground and then was managed flawlessly by Matt and his professional team. Matt and his team made many recommendations for keeping the project focused and maintaining its lively coverage.

Jessica Campilango, our editorial coordinator, assisted our authors and me during the many phases of its development. I am grateful for all her support. When it came to the production phase, the superb Wiley production team took over. Particularly I want to thank Deborah Schindlar and Miriam Palmer-Sherman, our production editors. I am grateful for all their hard work. I also want to thank Lynn Lustberg, our project manager from ICC Macmillan Inc. Her thoroughness made it easier to complete the project. I am grateful to all her efforts. I thank Kim Dayman and Christine Kim, our marketing team, for their impressive marketing campaign launched on behalf of the *Handbook*.

Last, but not least, I want to thank my wonderful wife, Nooshin, and my two children, Mohsen and Morvareed, for being so patient during this venture. They provided a pleasant environment that expedited the completion of this project. Mohsen and Morvareed assisted me in sending out thousands of e-mail messages to our authors and reviewers. Nooshin was a great help in designing and maintaining the authors’ and reviewers’ databases. Their efforts are greatly appreciated. Also, my two sisters, Azam and Akram, provided moral support throughout my life. To this family, any expression of thanks is insufficient.

Hossein Bidgoli
California State University, Bakersfield

Guide to The Handbook of Computer Networks

The Handbook of Computer Networks is a comprehensive coverage of the relatively new and very important field of computer networks and telecommunications systems. This reference work consists of three separate volumes and 202 different chapters on various aspects of this field. Each chapter in the Handbook provides a comprehensive overview of the selected topic, intended to inform a broad spectrum of readers, ranging from computer network professionals and academicians to students to the general business community.

In order that you, the reader, will derive the greatest possible benefit from *The Handbook of Computer Networks*, we have provided this Guide. It explains how the information within it can be located.

Organization

The Handbook of Computer Networks is organized to provide the maximum ease of use for its readers. All of the chapters are arranged logically in these three volumes. Individual volumes could be used independently. However, the greatest benefit is derived if all three volumes are investigated.

Table of Contents

A complete table of contents of the entire Handbook appears at the front of each volume. This list of chapter titles represents topics that have been carefully selected by the editor-in-chief, Dr. Hossein Bidgoli, and his colleagues on the Editorial Board.

Index

A Subject Index for each individual volume is located at the end of each volume. This index is the most convenient way to locate a desired topic within the Handbook. The subjects in the index are listed alphabetically and indicate the page number where information on this topic can be found.

Chapters

The author's name and affiliation are displayed at the beginning of the chapter. All chapters in the Handbook are organized according to a standard format as follow:

Title and Author

Outline

Introduction

Body

Conclusion

Glossary

Cross References

References

Outline

Each chapter begins with an outline indicating the content of the chapter to come. This outline provides a brief overview of the chapter, so that the reader can get a sense of what is contained there without having to leaf through the pages. It also serves to highlight important subtopics that will be discussed within the chapter. For example, the chapter "The Internet Fundamentals" includes sections for Information Superhighway and the World Wide Web, Domain Name Systems, Navigational Tools, Search Engines, and Directories.

The Outline is intended as an overview and thus it lists only the major headings of the chapter. In addition, second-level and third-level headings will be found within the chapter.

Introduction

The text of each chapter begins with an introductory section that defines the topic under discussion and summarizes the content of the chapter. By reading this section the readers get a general idea regarding a specific chapter.

Body

The body of each chapter discusses the items that were listed in the outline section of each chapter.

Conclusion

The conclusion section provides a summary of the materials discussed in a particular chapter. This section leaves the readers with the most important issues and concepts discussed in a particular chapter.

Glossary

The glossary contains terms that are important to an understanding of the chapter and that may be unfamiliar to the reader. Each term is defined in the context of the particular chapter in which it is used. Thus, the same term may be defined in two or more chapters with the detail of the definition varying slightly from one chapter to another. The Handbook includes approximately 2700 glossary terms. For example, the chapter "The Internet Fundamentals" includes the following glossary entries:

Extranet A secure network that uses the Internet and Web technology to connect two or more intranets of trusted business partners, enabling business-to-business, business-to-consumer, consumer-to-consumer, and consumer-to-business communications.

Intranet A network within the organization that uses Web technologies (TCP/IP, HTTP, FTP, SMTP, HTML, XML, and its variations) for collecting, storing, and disseminating useful information throughout the organization.

Cross References

All the chapters in the Handbook have cross references to other chapters. These appear at the end of the chapter, following the chapter text and preceding the References. The cross references indicate related chapters that can be consulted for further information on the same topic. The Handbook contains more than 2000 cross references in all. For example, the chapter “The Internet Fundamentals” has the following cross references:

Electronic Commerce, Electronic Data Interchange (EDI), Electronic Payment Systems, History of the Internet, Internet2, Internet Domain Name System, Information Retrieval on the Internet.

References

The References appears as the last element in a chapter. It lists recent secondary sources to aid the reader in locating more detailed or technical information. Review articles and research papers that are important to an understanding of the topic are also listed. The References in this Handbook are for the benefit of the reader, to provide references for further research on the given topic. Thus, they typically consist of a dozen to two dozen entries. They are not intended to represent a complete listing of all materials consulted by the author in preparing the chapter.

PART 1

Distributed Networks

Client/Server Computing Basics

INTRODUCTION

The name of an information system often describes the utility it provides. One can deduce that a transaction-processing system processes transactions, a decision-support system supports decisions, and an executive information system supports executives. However, client/server computing is not. Rather than describing an information system's utility, client/server is used more broadly to describe a system's architectural configuration. Moreover, the term client/server computing also incorporates a broad range of technologies and addresses a variety of business situations.

Client/server computing is a form of cooperative processing. Specifically, a client/server system includes at least two software processes working together to provide application functionality. At the most basic level, a client's software process requests services from a server's software process. For example, any time a user requests a Web page from a Web server (e.g., using the Internet to access a Web site), she/he is using client/server computing. That is, a client's application (e.g., a Web browser) is supported by a server's application (e.g., a Web server). In addition to Web pages, a client may also request from different servers a myriad organizational resources and services, such as e-mail, databases, printers, and files.

Client/server computing involves the coordination of assorted computing/networking devices and the coordination of various software processes. That is, the former (the client/server system architecture) describes the physical configuration of the computing and networking devices whereas the latter (the client/server software architecture) describes the partitioning of an application into multiple software processes.

The system architecture focuses on the physical architecture of the system. In this context, clients and servers are seen as computers rather than as software processes. In the most general sense, client/server system architectures include a client system (typically, a personal computer) that is connected to a server system (typically, a personal or midrange computer) using a network (e.g., a local area network). Each computer provides processing and memory resources to the client/server application. The system architectural perspective views a client/server

application as a network of computers sharing resources to solve a problem.

The client/server software architecture describes the partitioning of an application into software processes. In this context, clients and servers are seen as software processes rather than as computers. These processes may reside on the same computer or they may be distributed across a network of computers. The software architectural perspective views a client/server application as a set of programming modules sharing resources to solve a problem.

This chapter focuses on the client/server software architectural perspective; consequently, a client shall refer to a software process that requests services from other software processes and a server shall refer to a software process that provides services to other software processes. In this context, it is important to distinguish client/server computing from peer-to-peer computing. Specifically, client/server computing is predominantly asymmetric whereas peer-to-peer computing is more symmetric in orientation. That is, in client/server computing, application processes are typically designed to satisfy specialized functions whereas in peer-to-peer computing each computer requests and provides a variety of less sophisticated functions. In this chapter, we concentrate on the former—client/server computing.

The structural motivations of client/server computing include providing flexible, interoperable, and scalable programmatic solutions. Flexibility describes the extent to which a process can be modified for use by other applications. Client/server flexibility is sustained through detailed documentation and well-structured, well-defined process functionality. Interoperability is the extent to which two or more processes are able to exchange and share information. In that a client/server application is physically partitioned into a set of two or more processes, all client/server applications must provide highly interoperable solutions. Scalability is a measure of the extent to which an application can handle increased workload/throughput typically associated with adding extra computing resources or computing burden.

The practical motivations of client/server computing include: striving to share computing and information resources, exploring the usage of lower-cost technologies,

centralizing administration, and leveraging the relative strengths of desktop and back-office computing resources. For example, bug fixes and application enhancements can be made without having to deploy the revision to potentially thousands of client machines. In addition, since a server process typically provides services to many client processes, a client/server application can therefore provide unprecedented sharing of both computing and information resources. Moreover, a client's process is typically executed on a local desktop computer while a server's process is often executed on a back-office computer, thereby distributing the overall processing load. Furthermore, the increased utilization of less expensive desktop computers to provide such things as presentation services off-loads the computing burden from the more expensive back-office computers. Lastly, placing the data-centric processes on back-office computers provides improved systems management, data management, and administrative capabilities.

Client/server computing, however, has several notable disadvantages. For example, the initial design, development, and implementation can be quite costly. That is, client/server solutions often require additional physical (e.g., cables, hubs, routers) and software-based resources (e.g., network operating system). Moreover, client/server solutions can be quite complicated in that they use multiple, heterogeneous resources. As a result, an increase in potential points of failure emerges, as does the complexity of communications. These characteristics increase the system maintenance and support burden. However, in full consideration of the aforementioned advantages and disadvantages, the total-life-cycle cost of a client/server solution is thought to be significantly lower than comparable, traditional applications (e.g., client-based and server-based architectures).

This chapter begins with a review of three common client/server classification methods, namely the three-layered, the tier-based, and server functionality schemes. The subsequent section describes three broad categories of enabling technologies. These include middleware, component-based middleware solutions, and networking technologies. Next, since the Internet is the world's largest client/server environment, we briefly introduce the basic foundations of the Internet (e.g., Networking access, networking core, and networking edge) and the underpinnings for interoperability (e.g., the Internet protocol stack). The final section of this chapter reviews intranets, extranets, and the Internet, three popular client/server environments.

CLIENT/SERVER SOFTWARE CLASSIFICATIONS

A client/server classification provides information about a particular system architectural configuration. Three client/server classifications are reviewed below. The first classification, the three-layer architecture, describes the computational role of the client process—that is, how an application distributes its presentation, application processing, and data services. The second classification, the tier-based architecture, describes the number of

separate processes of a client/server application. That is, it classifies a client/server application based on the number of constituent processes. The final classification, server functionality, describes the primary functional role of server processes.

Three-Layer Client/Server Classification

Client/server computing divides an application into two or more separate processes. The three-layered architecture describes the computational role of both the client and server processes (it is important to note that the three-layered architecture is synonymous with the presentation-application-data, or PAD, architecture, however, the latter term has fallen out of favor and has subsequently been replaced by the former). In particular, the three-layered architecture defines the computational requirements of an application in terms of presentation services, application services, and data services. The presentation services layer details the interaction between the user and the application. The application services layer includes the embedded programming and business logic. The data services layer describes the connectivity to organizational resources such as data, printers, and e-mail (Goldman, Rawles, and Mariga 1999). Each of these services—presentation, application, and data—is discussed next.

Presentation Services

Presentation services describe the relationship between an application and the external environment. At the most basic level, these interactions involve user input and application output. A user's input represents the portion of her or his knowledge submitted to an application. Input provides data and system operating parameters (a.k.a., user instructions to the system on what is being requested). The purpose of application output is to provide new knowledge in the form of printed reports, audio signals, screen displays, and data. In many cases, a client/server application receives input from and provides output to multiple sources, such as other users, other software processes, and/or other applications.

Presentation services can also influence the degree to which a person will use, as well as how they will use, an application. That is, a complex, synergistic relationship exists among the user, the business problem/context, and the application (Dix, Finlay, Abowd, and Beale 1998). Several areas of study are dedicated to investigating how people and technology interact; these include, but are not limited to, cybernetics, human-computer interaction, ergonomics, human factors analysis, technology acceptance and adoption, and industrial engineering.

Application Services

Application services describe how input is transformed into output. The application services layer represents the procedural knowledge (i.e., business logic) embedded in the application. These include statistical, mathematical, graphical, and/or data transformational services.

Data Services

Data services provide access to organizational resources including information-based resources (e.g., databases),

hardware-based resources (e.g., printers), and communication-based resources (e.g., e-mail). The data services layer provides utility to the application services layer and/or the presentation services layer.

In general, the three-layered architecture classifies client/server applications based on the distribution of computational services between the client process and the server process. As seen in Table 1, the three-layered architectural framework includes five client/server classification levels. Each level is defined by the client-side functionality—that is, the extent to which it meaningfully participates in presentation, application, and data services.

In the first level, distributed presentation, the client shares the presentation processing with the server and the server handles all application and data services. In the second level, local presentation, the client handles the presentation services and the server handles the application and data services. In the third level, distributed application logic, the client addresses the presentation services and a portion of the application services; the server handles the data services and shares the application services with the client. In the fourth level, local application logic, the client handles the presentation and application services and the server handles the data services. In the last level, distributed data services, the client handles all presentation and application services and the data services are shared by the client and the server. Conceptually, as an application moves along the above continuum—from a distributed presentation to a distributed data service—it is also moving from a thin to a thick client.

Tier-Based Client/Server Classification

Client/server computing partitions an application into two or more separate processes. The client/server tier-based classification method views each software process as a computational component/layer/tier within the overall application. Three tier-based classifications will be discussed in detail below (e.g., two-, three-, and n -tier); however, before doing so, it is best to first review their predecessors, namely, host-based and client-based computing.

With host-based computing, the server performs all services (Figure 1). That is, the server (usually a mainframe in this context) is responsible for the presentation, application, and data (access and storage) processes while the client (usually a terminal in this context) merely accepts input from and displays output to the user. Compared to tier-based computing, host-based computing encountered two fundamental problems. First, the server had to process all user requests, which, in many cases, created a bottleneck for the network. Second, in order to remedy the first limitation, organizations were required to make expensive (e.g., in excess of \$100,000) and bulky upgrades to their mainframes (IBM 2006).

As desktop computation power increased and as cost decreased, organizations began to shift away from host-based to client-based computing. In a client-based architecture, the client is responsible for the presentation, application, and data processing while the server is responsible for data storage (Figure 2) (e.g., file server). Like host-based computing, client-based computing experienced several key limitations. First, the network emerged as a bottleneck. For example, in client-based

Table 1: Three-Layered Architectural Framework of Client/Server Applications

	Thin Client/Server			Thick Client/Server	
	Application			Application	
Computational Service	Distributed presentation	Local presentation	Distributed application logic	Local application logic	Distributed data services
Presentation services	Shared	Client	Client	Client	Client
Application services	Server	Server	Shared	Client	Client
Data services	Server	Server	Server	Server	Shared

Figure 1: Host-based architecture

Figure 2: Client-based architecture

Figure 3: Two-tier client/server architecture

Figure 4: Three-tier client/server architecture

computing the database was often copied and transferred over the network in its entirety to the client before it could be queried. This resulted in the network circuit being overloaded (i.e., even if an application needed only a single record, all records had to be sent from the server to the client). Second, because the client performed nearly all the processing, it became a bottleneck as well. Lastly, data synchronization and sharing are problematic in client-based computing. To address these limitations, tier-based computing emerged.

A two-tier system is the simplest and oldest client/server architecture (Figure 3). In a two-tier system, a client interacts and communicates directly with a server. This architecture often strives to provide reusable, robust links to organizational resources, such as printers and data. In general, a two-tier system leaves most, if not all, the application processing to the client. As seen in Figure 3, the presentation and application processes reside on the client whereas the data access and data storage reside on the server. Compared to a purely host-based or client-based architecture, tiered-based

architectures provide two primary advantages. First, tier-based computing shares the computation burden among several machines. Second, the data access and data storage processes reside in a single location (unlike client-based solutions, which duplicate and transmit the database), thereby reducing the excessive demands placed on the network circuit.

In a three-tier system (Figure 4), a client communicates to a server through an intermediary process. This intermediary process provides functionality as well as connectivity. Middle-tier functionality may include message queuing, application execution, and database staging. The middle tier also provides encapsulation for the data source and abstraction for the presentation services. As a result, changes to the data structure and/or user interface are less disruptive and more transparent. Furthermore, data encapsulation improves connectivity with legacy and/or mainframe systems. As a result, a three-tier system may support a large number of concurrent users and is able to handle very complex processing (Carnegie

Figure 5: n -Tier client/server architecture

Mellon Software Engineering Institute, *Client/server software architectures*, 1997).

The n -tier client/server architecture (Figure 5) is a natural extension of the three-tier architecture. An n -tier system has an undetermined number of intermediary processes and server processes. A client process might call on a middle-tier process, which in turn might call on another middle-tier process. In combining narrowly focused processes together, the n -tier architecture is used to provide both application flexibility and software reusability.

In the next section, server functionality is discussed.

Server Functionality Classification

Many client/server applications strive to reuse functionality among many applications. Because a server process often embeds and hides complicated implementation details, reusing a process significantly reduces system development time and effort. Furthermore, reusing successful, robust server processes improves overall system reliability (Weiss 2001).

To promote reusability the descriptive name of a server process often describes the functionality of the process. The following list describes a few server types. Table 2 provides a summary of the servers listed below.

Web Server

A Web server creates a standardized way for objects to communicate with each other over the Internet. A Web server provides session connectivity to clients running Web browsers (e.g., Internet Explorer, Netscape, Firefox, etc.). Early Web servers fetched files for clients without processing or interpreting the content. However, technologies such as Common Gateway Interface (CGI), Active Server Pages (ASP and ASPX), Java Server Pages (JSP),

Java Servlets, eXtensible Markup Language (XML), and XML-based Web services have dramatically expanded the processing and interactive capabilities of Web servers.

Application Server

Application servers provide interactive and processing functionality to clients. An application server may perform programming logic, store and process information, and/or manage user interactivity. Centralizing programming logic allows developers to reuse existing, proven application functionality as well as to simplify software version control, bug fixing, and software deployment.

Wireless Server

A wireless server provides network and Internet connectivity for wireless devices. Two popular wireless servers are wireless enablers and wireless gateways. A wireless enabling server stores information specifically designed for wireless devices, such as wireless markup language (WML). WML is a wireless-friendly version of hypertext markup language (HTML). A wireless client accessing a wireless enabling server would be provided with a WML file rather than an HTML file. Unlike a wireless enabler, a wireless gateway typically does not store content. It accepts requests from wireless and traditional devices and routes each request to an appropriate server based on the request and device type. Some wireless gateway servers also translate wireless and traditionally formatted messages to and from WML and HTML. These translations allow wireless devices to access both traditional and wireless content.

Transaction-Processing (TP) Monitoring Server

A transaction-processing (TP) monitoring server introduces performance efficiencies when serving a large

Table 2: Functional Descriptions for Several Server Types

Server Type	Functional Description
Web server	Connectivity and interactivity to clients running Web browsers
Application server	Interactivity and processing functionality
Wireless server	Wireless content-locating services and/or wireless-friendly content
Transaction-processing (TP) server	User responsiveness, processing prioritization, scheduling, and balancing
Message server	Message routing and delivery
E-mail server	Electronic-mail storage, routing, and delivery
Fax server	Fax storage, routing, and delivery
Proxy server	Intermediary content and processing functionality
Firewall	Access restriction based on a predetermined set of security criteria
Dynamic host configuration protocol (DHCP) server	Dynamic reuse of network addresses
File transfer protocol (FTP) server	File transfer capabilities

number of users. These servers accept client requests, merge requests together by type, and then transmit the resulting consolidated messages to appropriate servers. In sum, a TP can be used to monitor, prioritize, schedule, process, balance, and/or rollback service requests.

Message Server

A message server accepts and routes messages. A message is a service request that is packaged with destination information. An e-mail request is a message; it has embedded intelligence regarding the specific message destination. Thus, an e-mail server is a message server.

E-mail Server

An e-mail server accepts, routes, stores, and delivers electronic mail (e-mail) messages; it handles incoming and outgoing e-mail messages. Several e-mail standards exist, such as the Internet e-mail standards (SMTP—Simple Mail Transfer Protocol; IMAP—Internet Message Access Protocol; POP-3—Post Office Protocol), X.400, and Microsoft's Messaging Application Programming Interface (MAPI).

Fax Server

A fax server is similar to an e-mail server. It accepts, routes, stores, and delivers faxes; it handles incoming and outgoing faxes. Most fax servers provide additional features such as a direct-to-print option (i.e., allowing a fax to be sent to a printer rather than an electronic inbox).

Proxy Server

A proxy server is an intermediary process. It intercepts client requests and attempts to satisfy each request itself. If a request cannot be satisfied, the proxy server routes the request to an appropriate server.

A proxy server can be used to control and manage Internet usage. For example, by channeling all client requests through an organization's proxy server, a firm can monitor and/or limit Internet usage. A proxy server can also optimize Internet usage by using a local cache of Web pages. In addition, it reduces security threats by limiting Internet access to a single machine. A proxy server that filters Internet requests and/or logs Internet usage is acting as a firewall.

Firewall

A firewall reduces the risks associated with unauthorized access to a network and inappropriate use of networking resources. All requests entering and potentially leaving (depending on the configuration) a network must pass through a firewall. The firewall rejects requests that fail to satisfy the predetermined security criteria. Moreover, a firewall can also record user requests and network activities. In general, firewalls are configured based on organizational security and auditing concerns.

Dynamic Host Configuration Protocol (DHCP) Server

Like a postal address for a brick-and-mortar building, each computer on a network must possess a unique address (e.g., an IP address). Traditionally, these addresses were fixed, meaning: (1) each computer required individual configuration, (2) potential conflicts were inevitable, and (3) organizations were required to manage large blocks of addresses.

A dynamic host configuration protocol (DHCP) server dynamically assigns Internet addresses (IP addresses) to computers on the network. This permits an organization

to standardize computer configurations, to reduce network address contention, and to continually recycle a smaller number of network addresses.

File Transfer Protocol (FTP) Server

A file transfer protocol (FTP) server facilitates the transfer of files from one computer to another via a network. An FTP server accepts file uploads (i.e., copying files to a server) and file downloads (i.e., copying files from a server). Many FTP servers provide unrestricted access; however, others restrict access to authorized users only.

ENABLING TECHNOLOGIES

Enabling technologies allow heterogeneous software processes, computing devices, and networking devices to interoperate. Enabling technologies include technical standards, organizing frameworks, and product implementations. Three enabling technologies are discussed: middleware, component-based middleware, and networking technologies.

Middleware

Middleware is a primary enabler of client/server computing. Middleware acts like glue, holding together the separate software processes. Middleware products simplify the design, development, and implementation of complex applications by hiding the location of servers, networking protocol details, and operating system differences (Carnegie Mellon Software Engineering Institute, *Middleware*, 1997). Middleware is broadly defined; it may be a type of program-to-program interface, a set of standards, or a product. Table 3 provides a summary of the middleware categories listed below, namely transactional, message-oriented, and procedural.

Transactional Middleware

Transactional middleware supports the function of transaction processing. In particular, transactional middleware strives to provide responsiveness and data integrity while supporting a large number of users. It often includes load-balancing, replication, and/or two-phase commits. The Customer Information Control System (CICS) from IBM is a transactional middleware product. CICS is commonly used on IBM mainframes and on several other

IBM-platforms, including OS/2, AS/400, and RS/6000. The distributed transaction processing (DTP) protocol from the Open Group is another transactional middleware standard. Many relational and object-oriented database-management systems support DTP. BEA Tuxedo, from BEA Systems, is another popular transactional middleware product.

Message-Oriented Middleware

Message-oriented middleware (MOM) supports client/server processes using asynchronous, peer-to-peer messages. A MOM does not require continuous, active communication between the client and the server. That is, after a client sends a message, it does not wait for a response. If a server is busy or unavailable, any received message waits in a queue until it is reconciled/satisfied. A MOM solution is well suited for event-driven and object-oriented applications. However, many MOM implementations are proprietary. As a result, they tend to be inflexible and difficult to maintain, and they lack interoperability and portability (Carnegie Mellon Software Engineering Institute, *Message-oriented middleware*, 1997). MOM middleware products include WebSphere MQ (formerly MQSeries) from IBM, Microsoft Message Queue (MSMQ) from Microsoft, and Java Message Service (JMS) from Sun Microsystems. WebSphere MQ is a mature product supporting over 35 platforms (www.ibm.com). MSMQ is also a mature product extended to Microsoft's .NET environment (representing Microsoft's shift toward ubiquitous connectivity between information, people, applications, and devices—see www.microsoft.com/net). JMS is a Java application programming interface (API) included in the Java 2 Platform, Enterprise Edition (J2EE). JMS is one of the many standards included in J2EE, which is a platform for developing distributed applications using the Java programming language. J2EE specifies many services, including asynchronous communications using JMS, naming services using Java Naming, which is the Directory Interface (JNDI), transaction services using Java Transaction API (JTA), and database access services using Java Database Connectivity (JDBC). J2EE implementations are developed and provided by a variety of vendors (Sun, *Java 2 platform, enterprise edition (J2EE)*, n.d.; Alur, Crupi, and Malks 2001).

Procedural Middleware

A remote procedure call (RPC) supports synchronous, call/wait process-to-process communications. When using an RPC, a client requests a service then waits for a response. As a result, an RPC requires continuous, active participation from the client and the server. Each RPC request is a synchronous interaction between exactly one client and one server (Carnegie Mellon Software Engineering Institute, *Remote procedure call*, 1997). Open Network Computing Remote Procedure Call (ONC RPC), developed by Sun Microsystems and now supported by the Internet Engineering Task Force (IETF), was one of the first RPC protocols and is widely deployed to a variety of platforms. The Distributed Computing Environment (DCE), developed and maintained by the Open Group (formerly known as the Open Systems Foundation), is

Table 3: Middleware Categories and Implementation Examples

Middleware Category	Implementation Examples
Transactional middleware	CICS—IBM DTP—Open Group BEA Tuxedo—BEA Systems
Message-oriented-middleware	WebSphere MQ—IBM JMS—Sun Microsystems MSMQ—Microsoft
Procedural middleware	ONC RPC—IETF DCE RPC—Open Group

a set of integrated services supporting the development of distributed computing environments. DCE provides distributed services and data-sharing services, including RPC, directory services (i.e., the ability to identify and locate system resources), time services, security services, and thread services (i.e., the ability to build concurrent applications). DCE data-sharing services include diskless support and distributed file system services (Open Group 1996). DCE RPC is the protocol used by several object- and component-based middleware solutions, such as Microsoft's Distributed COM (DCOM) and COM+ and is also an optional protocol in the Object Management Group's Common Object Request Broker Architecture (CORBA).

Component-Based Middleware

Component software strives to improve software development productivity through the reuse of self-describing, self-contained software modules called "components." Each component provides specific functionality. An application discovers and calls on components at run-time.

Component software exists within a component model, which defines the way components are constructed and the environment in which a component will run. The component model consists of an interface definition language (IDL), a component environment, services, utilities, and specifications. An IDL defines how a component interacts with other components to form applications (see www.omg.org for CORBA's IDL). The components exist within a component environment—a computing environment providing the ability to locate, and communicate with, components. Several popular component models—both mature and emergent in nature—are presented in this section, including Object Management Group's CORBA, Microsoft's Component Object Model (COM), Sun Microsystems' Enterprise Java Beans (EJB), and Web Services. However, before each is presented, two brief comments regarding CORBA and Web Services, as they relate to COM and EJB, are presented.

First, relative to COM, COM+, and EJB, CORBA is a lower-level architecture; however, because it is regaining popularity as a viable interoperability solution (e.g., between JAVA and .NET), as well as being embraced by other popular computing platforms (e.g., Linux), it is included in the current context (e.g., Donner 2004; Harmon 2004). Second, Web Services, although not a traditional, component-based middleware architecture per se, is nonetheless discussed in the current context in terms of an emerging, higher-level solution to the challenges of heterogeneity in distributed, component-based computing environments.

Common Object Request Broker Architecture (CORBA)

CORBA is an open, vendor-independent, mature architecture describing object-oriented process interactions over a network. CORBA, supported by the Object Management Group (OMG), uses a standard communication protocol IIOP (Internet Inter-ORB protocol). IIOP allows a CORBA process running on one computer to interact with a CORBA process running on another computer

without regard to network, vendor, programming language, or platform heterogeneity. CORBA supports a variety of services, including asynchronous and synchronous, stateless and persistent, and flat and nested transactions (OMG, n.d.).

Component Object Model (COM)

Microsoft's COM is a way for multivendor software components to communicate with each other. It provides a software architecture that allows applications to be built from binary components supplied by different software vendors. COM provides the foundation for many technologies, including object linking and embedding (OLE), ActiveX, and Microsoft Transaction Server (MTS). Distributed COM extends COM by allowing remote component interactions. COM+ further expands COM by encapsulating DCOM, MTS, and a host of other services, including a dynamic load-balancing service, an in-memory database, a publish-and-subscribe events service, and a queued-components service. COM components require the COM application server, available on the Windows operating system platforms (Microsoft 1998).

Within Microsoft's .NET (pronounced "dot net") environment, material modifications to both COM and COM+ have taken place. The runtime environment known as COM+ has been absorbed into the .NET Enterprise Services space (see www.microsoft.com/net).

Enterprise Java Beans

Similar to CORBA, Sun Microsystems' Enterprise Java Beans (EJB) is a specification. An EJB must be programmed using Java and must be hosted on a J2EE application server. EJBs interact with each other using Java Remote Method Invocation (RMI). RMI is a set of APIs used to create distributed applications using Java; it is also an implementation that operates in a homogeneous environment using a Java virtual machine (JVM). RMI allows Java objects to communicate remotely with other Java objects (the Microsoft platform parallel is .NET Remoting—see <http://msdn.microsoft.com>). Alternatively, an EJB built with an implementation based on the EJB 2.0 specification, or higher, may communicate using the message-oriented-middleware, JMS (Marinescu and Roman 2002).

An EJB system consists of three parts, the EJB component, the EJB container, and the EJB object. An EJB component exists within an EJB container running on an EJB server. The EJB object provides access to the EJB components. An EJB component is a software module that provides specific functionality; it may be discovered and manipulated dynamically at run-time. The EJB container provides the execution environment for the EJB components; it handles the communication and interface details. An EJB container may support more than one EJB component. Whereas an EJB component runs on a server, an EJB object runs on a client. An EJB object remotely controls the EJB component (Sun, *Java remote method invocation*, n.d.).

Web Services

Although not traditional middleware per se, Web services represent a critical paradigm shift in middleware:

service-based computing. Web services represent the first successful cross-platform component architecture outside traditional component-based models. Consequently, Web services have been included in this section. According to Microsoft, Web services represent a “self-describing software module, semantically encapsulating discrete functionality, wrapped in and accessible via standard Internet communication protocols like XML and SOAP” (Microsoft 2005). What that amounts to is a platform-independent module that builds on existing Internet standards, primarily XML, to provide, validate, and interpret data. Web services also conveniently leverage the HyperText Transfer Protocol (HTTP) to provide synchronous communications as well as the Simple Mail Transfer Protocol (SMTP) to provide asynchronous communications (e.g., e-mail).

Web services provide Internet-accessible, building-block functionality to developers; they allow for incremental development and deployment. Web services support new-application development and promise to provide access to existing applications. By wrapping traditional processes in Web service protocols, an existing computing infrastructure can improve interoperability and utilization without having to reprogram existing applications. Furthermore, an existing application may enhance functionality by integrating with new Web services.

Web services are distinctive in several ways. Whereas a traditional process is designed to provide functionality to a particular application, a Web service strives to provide global access to a very well defined, packaged process designed to provide specific functionality. A Web service is not duplicated or moved; it is simply called on as required at run-time by applications. Ultimately, online providers will provide access to Web services that can be called on on an as-needed basis. Furthermore, unlike other distributed application environments, such as CORBA, J2EE, and COM+, Web services do not dictate the underlying communications framework (Singh, Stearns, Johnson, et al. 2002), rather they act as a separate and distinct bridge that uses standard Internet protocols such as HTTP, XML, and TCP/IP.

Open, standardized interfaces are the heart of Web services. Standards define how a Web service communicates, how it exchanges data, and how it is located. The Simple Object Access Protocol (SOAP) is an XML-based protocol for exchanging information in a distributed environment. SOAP is platform-independent and consists of an envelope, a set of encoding rules, and a convention describing procedure calls. A SOAP envelope describes the contents of the message and how the message should be processed. The encoding rules describe the application-specific data types. The conventions describe remote procedure calls and responses. Other standards include the Web Services Description Language (WSDL) and the Universal Description, Discovery, and Integration (UDDI). WSDL defines the Web service interfaces, while UDDI allows developers to list/post new Web services as well as locate existing Web services (UDDI 2002).

In the next section, networking in the context of an enabling client/server technology is reviewed.

Networking

The Internet consists of host computers, client computers, routers, applications, protocols, and other hardware and software. As an organizing framework, these technologies may be categorized using three broadly defined functional areas, namely, network access, network core, and network edge (Table 4).

Network access describes how devices connect to the Internet. The network core describes the intercommunications among the computing and networking devices. The network edge describes those objects using the Internet such as clients, servers, and applications (Kurose and Ross 2001; Peterson and Davie 1999).

Network Access

An Internet access provider (IAP) provides Internet access. The structure of an IAP is roughly hierarchical. At the lowest level, a local Internet service provider (ISP) provides connectivity for residential customers and small businesses. The local ISP connects to a regional ISP. The regional ISP connects to a national/international backbone provider (NBP). The various NBPs interconnect using private connections and/or public network access points (NAPs) to form the backbone of the Internet.

To communicate with an IAP (or ISP), a connection must be established and maintained. Several connection alternatives exist, including dial-up, integrated services digital network (ISDN), asymmetric digital subscriber line (ADSL), hybrid fiber coax (HFC, via a cable modem), T-services (e.g., T1, T3, etc.), SONET (e.g., OC1, OC3, etc.), and wireless (e.g., radio, cellular, satellite, and microwave).

The Network Core

The network core describes how networking devices interconnect with each other. The backbone of the Internet is an extremely large mesh. Data are sent through this mesh using either circuit-switching or packet-switching channels. A circuit-switching network establishes and maintains a circuit (i.e., a specific network path) for the entire duration of an interaction. A circuit-switching network knows where to look for messages, and the data are

Table 4: Internet Networking Categories and Components

Internet Networking Category	Components
Network access	Internet access providers Internet connectivity: dial-up, ISDN, ADSL, HFC, wireless, T1/T3
Network core	Routers and bridges Data routing: circuit-switching, packet-switching
Network edge	Computers, users, applications Internet protocol stack

received in the order in which they are sent. A packet-switching network divides each transmission into a series of individually addressed packets. Since each packet is addressed and ordered, the network path need not be determined and packets may be sent using whatever data rate may exist at the time the message is transmitted. As a result, each packet might take a different path through the network at different transmission rates. The receiver of the message is responsible for unpackaging and resequencing the packets.

The Network Edge

The network edge consists of objects using the Internet, such as clients, servers, and applications. For one object to communicate with another object, the two must adhere to the same networking protocol. A protocol is an agreed-on set of rules governing a data transmission. The Internet supports a variety of protocols. Some protocols are competing, meaning they serve the same purpose; others are complementary, meaning they serve different purposes.

In the next section, a review of the Internet protocol stack (i.e., the foundation for interoperability) is presented.

Internet Protocol Stack

An Internet protocol stack is a framework used to organize and describe networking protocols. Each layer in a protocol stack serves a particular networking need, or needs, and describes how a given layer must communicate with adjacent layers. Furthermore, the lower layers of the stack provide a foundation for the upper layers (Kurose and Ross 2001; Peterson and Davie 1999). As seen in Table 5, the Internet protocol stack is a variation of the widely accepted OSI model. The Internet protocol stack has the following five layers: physical, data link, network, transport, and application. The application layer of the Internet protocol stack envelops the application, presentation, and session layers of the OSI model. A description of each layer of the Internet protocol stack follows.

Physical Layer. The physical layer of the Internet protocol stack describes the physical characteristics of the networking media. Media can be broadly categorized as guided or unguided. Guided media include copper wire and fiber optics. Unguided media include radio, microwave, and satellite. The media type influences bandwidth, security, interference, expandability, contention, and costs. Examples of physical layer protocols include Ethernet (IEEE 802.3), Token Passing (IEEE 802.5), Wireless (IEEE 802.11), transmission convergence sublayer (TCS) and physical medium-dependent (PMD) for asynchronous transfer mode (ATM), and transmission frame structures for T-carriers.

Data-Link Layer. The data-link layer of the Internet protocol stack describes how devices share the physical media. These protocols define host-host connections, host-router connections, and router-router connections. The primary role of data-link-layer protocols is to define flow control (i.e., how to share the media), error detection, and error correction. Data-link layer protocols include the point-to-point protocol (PPP) and the serial-line Internet protocol (SLIP), which allow clients to establish Internet connections with Web servers. Ethernet and ATM are also popular data link layer protocols.

Network Layer. The network layer of the Internet protocol stack defines host and application addressing. The Internet protocol (IP) assigns a unique number, called the IP address, to devices connected to the Internet. The IP address uniquely identifies every computer connected to the Internet.

Transport Layer. The transport layer of the Internet protocol stack defines how information is shared among applications. The Internet transport protocols include transmission control protocol (TCP) and, under certain instances, user datagram protocol (UDP).

TCP is a connection-oriented protocol. A TCP-based application establishes and maintains a connection for

Table 5: Comparison of the OSI Model and the Internet Protocol Stack

OSI Model	Internet Protocol Stack	Layer Description	Protocols
Application	Application	Specifies how applications and processes will communicate with each other	HTTP, FTP, SMTP, MIME, DNS, NFS. Middleware products: RPC, MOM, CORBA/IIOP, CICS, DTP
Presentation			
Session			
Transport	Transport	Specifies how information is transmitted	TCP, UDP SPX
Network	Network	Specifies host and application addressing	IP IPX
Data Link	Data Link	Specifies how the media are shared	PPP, SLIP, ATM, Ethernet
Physical	Physical	Specifies the physical characteristics of the media	IEEE802.3, IEEE802.5, IEEE802.11, Token Passing, TCS, PDM

the entire duration of each transaction. This connection provides reliability and congestion control. Applications using TCP include e-mail, file transfers, and Web browsing.

UDP is a connectionless protocol. A UDP-based application communicates by sending individual datagram packets. Datagrams support applications requiring large bandwidth and those tolerating some degree of data loss. Applications using UDP include telephony, streaming video, and interactive games.

Application Layer. The application layer of the Internet protocol stack defines application-application communications. For example, the HTTP protocol allows Web clients to locate, request, and subsequently interpret Web-based objects (e.g., HTML, VBScript, Jscript, Java Applets, JPG files, etc.). Application layer protocols abound; however, salient applications are briefly reviewed next.

SMTP allows user agents (e.g., Microsoft Outlook, Eudora, etc.) to send, receive, and store e-mail messages. Multipurpose Internet mail extensions (MIME) supports e-mail attachments. Post office protocol (POP3) and Internet message access protocol (IMAP) allow clients to download e-mail messages from e-mail servers. FTP allows file transfers between computers. The domain name system (DNS) resolves IP addresses and universal resource locator (URL) names. Telnet allows for remote terminal access over the Internet. The network file system (NFS) protocol allows for remote storage of files.

Networking Security Vulnerabilities

Networks suffer from many security vulnerabilities, including accessibility or altering of programs or data; intercepting, creating, or modifying data in transit; and blocking traffic. These attacks may involve social engineering, performing reconnaissance, launching denial of service attacks, impersonating users, or spoofing systems. A social engineering attack strives to manipulate or trick users and/or support staff into divulging sensitive information. These attacks may be direct, such as asking for a password reset, or they may be indirect, in which an adversary may infer or derive sensitive information from the responses of several “individually nonsensitive” questions. Reconnaissance is an information-finding activity. Adversaries may engage in reconnaissance activities ranging from searching through physical and virtual recycle bins to analyzing design diagrams and configuration information. A port scan is a common reconnaissance activity. A port is a virtual communications channel used by specific applications. A port scan is a program that systematically searches hosts to determine available ports and what applications are using them. A denial of service attack inundates a server with requests in order to overwhelm and significantly reduce the performance of the system. Impersonation is when a party assumes the identity of another person or process or host. Spoofing occurs when an adversary acts on behalf of another party. Spoofing includes masquerading and session hijacking. Masquerading involves pretending to be someone else. Session hijacking involves intercepting a connection that has been established by another party. For an in-depth

review of these and other network vulnerabilities, see the chapters on Social Engineering, Intrusion Detection Systems, Network Attacks, Worms and Viruses, and Denial of Service.

In the next section, three popular client/server environments are reviewed.

CLIENT/SERVER ENVIRONMENTS

The Internet is exemplary when it comes to client/server environments. In this section we discuss the Internet as well as proprietary-based Internet environments—intranets and extranets.

Internet

The Internet is a network of networks. Hundreds of millions of computers, users, and applications use the Internet. The Internet uses a variety of protocols, including TCP/IP, HTTP, and FTP. The Internet supports Web browsing, online chat, multi-user gaming, e-mail delivery, fax delivery, and telephony, to name just a few.

As previously mentioned, the Internet typifies client/server computing. That is, resources, service, and processes are distributed, and thus shared, among and between multiple devices/users. However, when these resources are limited to a set, or possibly sets, of prespecified users (e.g., customers, employees, supply chain partners, vendors), two new internetworking environments emerge, namely intranets and the extranets.

Intranet

An intranet is a private network using the same technologies and protocols as the Internet. Since the foundation, protocols, and toolsets are the same, an intranet looks, feels, and behaves like the Internet. The difference between an intranet and the Internet is in both scope and access. That is, an intranet user is limited to visiting only those Web sites owned and maintained by the organization hosting the intranet, whereas an Internet user may visit any publicly accessible Web site. Since intranets are private, individuals outside the organization are unable to access intranet-based resources—that is, without specific organizational permission and technology (e.g., a virtual private network). As a result, organizations may publish internal and/or confidential information such as organizational directories, company policies, promotion procedures, and benefits information. The primary means of separating an intranet from the nonsecure, public Internet is a firewall.

Extranet

An extranet is an intranet that provides limited connectivity via the public Internet. Specifically, an extranet allows authorized Internet users to access a portion of a company's intranet. External access to a company's intranet is granted through a firewall and is typically facilitated via a virtual private network (VPN). That is, an Internet visitor either submits a username and password to the firewall or to an organization-provided VPN server.

If authenticated, the visitor is permitted limited access to the company's intranet.

Extranets are designed to interconnect suppliers, customers, and other business partners. The exposure of the extranet is based on the relationships a company has with its partners and the sensitivity of the content stored on the company's intranet. In the most relaxed scenario, individuals gain access to common business materials by completing a brief survey. In more restrictive scenarios, an organization may sign a contract detailing acceptable use of intranet resources or may require users to pay subscription fees. Extranets are also commonly used to support field personnel and employees working from Internet-based locations outside an organization's firewall.

CONCLUSION

Client/server computing is so broadly defined, that the name says little about a particular system. A client/server application may provide national security services to a government or it may provide publicly available editorials and commentaries. In addition, client/server computing encompasses several architectural interpretations. The client/server system architecture describes the physical configuration or topology of computing and networking devices. In this context, clients and servers are seen as computers. The client/server software architecture, however, describes the configuration of software processes. In this latter context, clients and servers are seen as software processes. Furthermore, client/server computing uses an enormous array of heterogeneous technologies, protocols, platforms, and development environments. Whereas some client/server applications are relatively simple, involving only a few technologies, others are extremely complex, involving a large variety of technologies.

Common to all client/server systems is the partitioning of an application into separate processes and the utilization of a communications mechanism (almost always a computer network). Two general categories of processes exist, those that request services (i.e., clients) and those that provide services (i.e., servers). A client process works together with a server process to provide application functionality.

A client/server classification provides information that describes a particular system. A classification may describe the computational role of the processes, the physical partitioning of an application into tiers, or the functional role of the processes. Although these classification methods help describe systems, they also serve to highlight the variety and complexity among client/server applications. The computational and functional role of the processes varies from system to system. Furthermore, a client may interconnect with many servers and a server may interconnect with many clients.

Enabling technologies strive to provide seamless integration of hardware and software in complex environments. Specifically, middleware governs the interactions among the constituent software processes. Component-based middleware provides the ability to create applications using existing, self-contained software modules

while various networking technologies bridge the gaps among computing and networking devices.

Early distributed computing consisted of vendor- and platform-specific implementations. However, the trend in client/server computing is to provide standardized connectivity solutions. Web services represent one of the most promising new client/server developments. Web services strive to leverage the communication infrastructure of the Internet to deploy client/server applications. Although it is too early to know whether Web services will fulfill their potential, they promise to change the way application programs are developed and deployed. As the excitement, investment, and standardization in such technologies continue to grow, so too will the global impact of client/server computing.

GLOSSARY

Client Process: A software program that requests services from one or more server processes.

Client System: A computer that supports a client process and requests services from one or more server systems.

Client/Server Software Architecture: The logical and physical partitioning of an application into software processes.

Client/Server System Architecture: The architectural configuration of computing and networking devices supporting a client/server application.

Client/Server Tier: A well-defined, separate process representing a portion of a client/server application.

Component: A self-contained, self-describing software module that provides specific functionality, in which several can be combined to build larger applications.

Component Environment: A computing environment providing the ability to locate and communicate with components.

Component Model: The way components are constructed and the environment in which a component will run, consisting of an interface definition language, a component environment, services, utilities, and specifications.

Enabling Technology: Technology that provides a client/server application with the ability to locate, communicate with, and/or integrate the constituent processes.

Extranet: An Intranet that provides limited access to/from the Internet using firewall technology.

Interface Definition Language (IDL): Defines how a program may communicate with a component.

Internet: A global network of networks supporting hundreds of millions of computers, networking devices, applications, and users.

Internet Protocol Stack: A subset of the OSI model; a framework that organizes and describes Internet networking protocols.

Intranet: A private network based on Internet protocols and technologies.

LAN (Local Area Network): A computer network that is located within a small geographical area, such as an office or small building.

Middleware: The software governing the interaction among the client and server processes.

n-tier system: An application that is partitioned into an unspecified number of separate processes that work together to provide system functionality.

Network: A series of points connected by communication circuits. See LAN.

OSI Model: A general framework that organizes and describes networking protocols.

PAD Architecture: Defines an application in terms of the following three computational services: presentation services, application services, and data services.

Process: An executing program.

Server Process: A software program that provides services to one or more client processes.

Server System: A computer that supports a server process and provides services to one or more client systems.

Three-Tier: An application that is partitioned into three separate processes that work together to provide system functionality.

Two-Tier: An application that is partitioned into two separate processes that work together to provide system functionality.

Designing Groupware	21		

INTRODUCTION

Groupware applications denote any type of software application designed to support groups of people in communication and collaboration on shared information objects (Ellis et al. 1991; ter Hofte 1998). The fundamental property of groupware is its ability to mediate the results of some user interactions to other people. Well-known types of groupware include e-mail, videoconferencing, work-flow, chat, and collaborative editing systems.

Contrary to optimistic predictions in the 1970s and 1980s, groupware applications, especially videoconferencing systems, have not reached their anticipated potential. For instance, Snyder (1971) predicted that by the end of the 1970s a full 85 percent of all meetings would be electronically mediated. Obviously, this has not been the case. On the other hand, some types of computer-supported cooperation have become highly successful, such as e-mail and instant messaging (ter Hofte, Mulder, Grootveld, and Slagter 2002). Understanding in what situations groupware is an effective and efficient means to support collaboration (and thus understanding its potential) remains an important research question even today.

GROUPWARE FUNCTIONALITY

Although there is a lot of diversity in groupware applications, some typical functionality is provided by many different applications. This section provides a list that, while not being exhaustive, represents a wide range of important functionality.

- *E-mail*: Primarily text-based, asynchronous electronic form of person-to-person or person-to-group communication. The term e-mail is applied both for communication via the simple mail transfer protocol (SMTP) as well as the generic groupware functionality to send electronic messages to other people. As central servers are used to store e-mail messages, the collaborating people do not have to be online at the same moment to exchange e-mail messages.

- *Instant messaging*: Sometimes referred to as chat, instant messaging is primarily about text-based communication between a specific group of people who are online at the same moment. Such same-time collaboration is denoted as synchronous collaboration. Instant messaging is usually combined with presence awareness information about a list of contacts, sometimes denoted as buddies. This presence awareness information indicates which of your contacts are currently available for communication.
- *Discussion forum*: Primarily text-based communication via threaded discussions. A discussion forum supports asynchronous collaboration, meaning the collaborating people do not have to be online at the same moment. In contrast to e-mail, discussion forum messages are centrally stored, not sent to one or more people. The centrally stored messages can be accessed by multiple people, and typically people can react by messages as well. People who join a forum can also typically read and participate in previously started discussion. In a forum, messages and associated reactions are grouped in so-called threads.
- *Newsgroup*: A newsgroup is a specific type of discussion forum, typically part of the Usenet hierarchy, a distributed Internet discussion system.
- *Videoconferencing*: Refers to functionality that allows two or more locations to synchronously interact via two-way video and audio connections. Video conferencing systems may be room-based, allowing for groups to interact, or desktop-based, which is more focused on individuals.
- *Audioconferencing*: Refers to functionality that allows two or more locations to synchronously interact via two-way audio connections. Although audio conferencing primarily takes place via normal telephones and cell phones, there are also software tools that use the internet protocol (IP) for voice communication. The latter applications are typically referred to as voice over-IP (VoIP) applications.

- *Network games*: Refers to collaboration functionality primarily aimed at entertainment or enjoyment, although it may also serve as exercise or perform an educational, simulation or psychological role.
- *Group calendar*: Refers to functionality that allows groups of people to coordinate their actions by sharing calendar information. In a basic setting, people can view whether another person is free or busy at a specific time, but in more advanced cases they can have a detailed look at the appointments in other people's schedules. Group calendars are typically used within the context of one organization, given the sensitivity of the shared information. Group calendars require up-to-date information and a critical mass of users, before they become effective to coordinate actions.
- *Shared whiteboard*: Refers to functionality to create, edit, and share drawings, based on the white board metaphor. Shared white boards can be used for synchronous as well as asynchronous forms of collaboration.
- *Application sharing*: Functionality that allows you to synchronously collaborate using applications that were not designed to be used in a collaborative way. Application-sharing functionality typically allows one of the participants to provide input to a shared application, while the application output is distributed to all collaborating people. Typically, some coordination policy is in place to decide who is in control of the shared application. There are two main versions of application sharing: window sharing and screen sharing. In window sharing, one specific application is shared, while in screen sharing, all collaborating people see exactly what is on the presenter's screen.
- *Group decision support system*: Abbreviated GDSS, this functionality refers to a suite of collaborative functionality to facilitate group decision processes. A GDSS can be used by colocated teams as well as by geographically dispersed teams, but typically it focuses on synchronous forms of collaboration. A GDSS usually includes brainstorming tools—tools to prioritize or cluster ideas and voting tools.
- *Workflow management*: Functionality to support (asynchronous) work processes. Workflow management systems allow users to define how tasks are structured and who performs them, when, and in what order. The collaborating users are informed of any tasks they are supposed to perform and the deadline. A workflow

management system keeps track of the progress and typically updates the task owner about the status of the process and any deviations in relation to the planning.

- *Shared workspace*: Refers to a suite of functionality to collaborate synchronously, but mostly asynchronously. Typical functionality includes file sharing and version control, notifications of changes to the workspace and access control to restrict who can view, edit, or delete content. Advanced shared workspaces integrate much of the above-mentioned functionality.
- *Wiki*: A Wiki is a type of Web site that allows users to easily add and edit content and is especially suited for asynchronous collaborative writing. Wikis typically reside on a central server and are served by a Wiki engine.

CLASSIFYING GROUPWARE APPLICATIONS

Historically, groupware applications have been classified based on the time-place matrix described by Johansen (1988). This matrix classifies groupware applications along two axes: whether the cooperating people work at the same time (synchronously) or at different times (asynchronously) and whether the people work at the same physical location or at different places. Table 1 represents this matrix with some example groupware applications positioned in it.

However, this time-place matrix is very rigid, and does not, for instance, allow for applications that support the transition between more synchronous and more asynchronous forms of cooperation, such as shared workspaces or applications to record and replay (virtual) meetings. Grudin ("Computer-supported cooperative work," 1994) extended this matrix to include the factor of "predictability": he argues that although people may not be working at the same time, there is an important difference between being able to predict when another person is likely to work and not being able to predict this. Similarly he has added a row to the matrix to distinguish whether it is possible to predict the place where the other people will be. The resulting matrix is shown in Table 2.

Given the focus of this handbook, most of the examples and design issues are about groupware applications that do not require cooperating people to work together at the same place.

Table 1: The Time-Place Matrix by Johansen

	Same time (synchronous)	Different time (asynchronous)
Same place (local)	Group decision support systems	Electronic project rooms
Different place (remote)	Videoconferencing, text-based chat, shared workspaces	E-mail, group scheduling, shared workspaces

Table 2: The Time-Place Matrix by Grudin

	Same time (synchronous)	Different time, but predictable (asynchronous)	Different time, unpredictable (asynchronous)
Same place (local)	Meeting facilitation	Work shifts	Team rooms
Different place, but predictable (remote)	Tele-, video-, desktop-conferencing	Electronic mail	Collaborative writing
Different place, unpredictable (remote)	Interactive multicast seminars	Computer bulletin boards	Workflow

Synchronous and Asynchronous Collaboration

Although the matrix by Johansen may be rigid, the distinction between synchronous and asynchronous (and any forms in between) is helpful in itself. Distinguishing different forms of collaboration and being able to select suitable groupware functionalities to support them is helpful when designing groupware support for a specific setting.

Table 3 illustrates that this is no dichotomy. In real-life settings, the situation may be even more blurred: whereas e-mail was designed as a tool to support asynchronous collaboration, sometimes messages and replies follow each other at such a rapid pace that it becomes a tool for synchronous collaboration.

Groupware applications designed for synchronous collaboration frequently apply the *conference* concept, denoted as a period of interaction by a group of cooperating people, supported by groupware functionality. During such a conference, a set of rules may apply to regulate access to groupware functions. A conference has a beginning and an end and is characterized by an explicit or implicit objective (e.g., a peer-review session, a project

progress meeting, a design session). In literature, such conferences are sometimes referred to as *sessions*. Functionality to manage conferences is therefore sometimes denoted as session management.

Peer-to-Peer and Client/Server Groupware

The terms *peer-to-peer* and *client/server* refer to the architectural model on which the groupware design is based (Figure 1). In the peer-to-peer groupware model, the different collaborating people each use a groupware application

**Figure 1:** Peer-to-peer versus client/server architecture**Table 3:** Groupware Functionality to Support Synchronous and Asynchronous Collaboration

(client) that connects directly with the groupware application of the other people. In the client/server groupware model, the groupware applications (clients) all connect to a central server, which relays messages and can provide shared services.

The differences between the two architectural models also have implications when using applications based on these models: peer-to-peer groupware applications provide users with more control over their data and avoid dependency on a third (economic) party to host a server. The peer-to-peer model is in line with current Internet trends, whereby the computing power and storage capabilities of network peripheral hosts are used. This is in contrast with the client/server model, in which much of the intelligence is allocated to a central, high-performance host.

However, the client/server model also has some clear advantages: centralizing functionality in a server allows for “thin clients” with a small footprint. This enables people, for instance, to access groupware functionality from their PDA or smart phone. In addition, a central server can act as a meeting point and to set up connections with other participants behind a firewall. And, obviously, a central server allows you to create shared workspaces that can be accessed asynchronously.

EXAMPLES OF GROUPWARE APPLICATIONS

Many groupware applications have emerged, both in academia and in industry, each providing particular support for cooperating people. Typically, groupware applications are designed to support a particular work situation or a particular range of cooperative work situations. Well-known examples of groupware applications include e-mail, audio- and videoconferencing applications, instant messaging applications, and applications to work together using shared virtual workspaces. This section introduces some well-known groupware applications, illustrating the diversity in current groupware applications.

BSCW

BSCW (Basic Support for Cooperative Work) (BSCW 2006) is a Web-based environment for collaboration (Figure 2). It started as a Web-based application to share files, but gradually turned into a shared virtual workspace that supports document sharing, online discussions and shows, as an example, participant status information such as who has viewed, edited, or downloaded a file. BSCW offers a fixed set of collaboration tools and depends on external tools for synchronous communication between workspace participants. The BSCW environment provides services to invite people to a shared virtual workspace, assign roles to people, and specify the rights associated with each role.

Lotus Notes

Lotus Notes (Lotus Notes 2006), shown in Figure 3, is an integrated cooperative environment that combines messaging, shared databases, calendaring, and scheduling functions with a platform to create collaborative applications. These collaborative applications are founded on replicated, shared databases that users can access and update through forms. Lotus Notes provides advanced security and role-based access control, related to workflow facilities. The Notes platform provides developers with integrated tools to create tailor-made cooperative applications, based on the specific requirements of a company. Lotus Notes’ databases and forms can be accessed via the Notes client, or be turned into Web applications using Lotus Domino (Lotus Domino 2006). In addition, Lotus Web Conferencing and Lotus Instant Messaging (previously known in their combined form as Lotus Sametime) provide awareness services to discover which contacts are currently online, and to start communication using text-based messages, audio, video, or application sharing. Although Lotus Notes offers a highly flexible environment, it requires programming skills to create and adapt cooperative applications.

Figure 3: Example screenshot of Lotus Notes

MediaWiki

MediaWiki is an example of a Wiki engine, software that allows people to easily create, edit, and share content on Web sites and is especially suited for collaborative writing (MediaWiki 2006). MediaWiki is free server-based software. The fact that a Wiki allows people to easily and quickly change content on Web sites makes it especially suitable to support creative team processes. A good example to illustrate the possibilities of Wikis is Wikipedia, an online encyclopedia written collaboratively by volunteers using the MediaWiki engine, allowing most articles to be changed by anyone with access to a Web browser (Wikipedia 2006).

Groove

The Groove Workspace by Groove Networks, Inc. (Groove Networks 2006) is a peer-to-peer groupware application that enables people to cooperate using shared virtual workspaces. In addition, it provides synchronous communication via text-based chat and audio conferencing. Groove workspaces provide a cooperation environment in which people can exchange information and collaborate using an extensible set of tools, including a shared schedule, a collaborative editor, a file-sharing tool, and a shared presentation viewer. The Groove application, shown in Figure 4, provides services to see which of your contacts are online or active in the workspace, to invite (and uninvite) people to a workspace, and to assign roles to people and specify the rights associated with a role. In addition, the Groove Workspace application makes use of a groupware infrastructure that provides some value-added services, such as security, firewall transparency, and workspace synchronization after a participant has been offline. To do so, the infrastructure applies central servers, in contrast to the overall peer-to-peer philosophy.

GroupSystems

GroupSystems is an example of a group decision support system (GDSS) that allows workgroups to collaborate either face-to-face or remotely over the Internet (GroupSystems 2006). The software supports group processes by offering a wide range of functionalities to generate ideas, distill, clarify, organize, evaluate, and build consensus. Typically, organizations use a GDSS to increase the efficiency of group processes such as brainstorming, strategic planning, focus groups, requirements gathering, and idea management. An additional benefit is that the software helps in capturing intermediate results and documenting the process.

Skype

Skype (Skype 2006) is a *voice over-IP (VoIP)* application, meaning that it allows you to communicate by voice over the Internet. In addition, the application offers instant messaging functionality and presence awareness, indicating which of your friends who also use Skype are currently available for communication. Apart from supporting computer-to-computer calls, Skype offers value-added services for computer-to-phone calling (SkypeOut) and phone-to-computer calling (SkypeIn). Skype users can activate voicemail functionality, which allows people to leave voice messages when they cannot reach someone.

Windows Messenger

Microsoft Windows Messenger (as well as the related product MSN Messenger) (Microsoft 2006) is an instant messaging application that allows people to communicate in a synchronous manner using text messages. The application, shown in Figure 5, shows the presence status of a list of contacts, providing clues as to whether they are

Figure 4: Example screenshot of a Groove workspace

Figure 5: Examples screenshots of Windows Messenger

available for communication. The Messenger application includes facilities for voice and video communication, file sharing, and the option to collaborate using application sharing. The application also provides services to invite additional people to an online conference. The Messenger application relies on external tools for asynchronous forms of communication. The application does not provide support for access control or workflow management.

DESIGNING GROUPWARE

Groupware Design Issues

Although the biggest challenge in designing a groupware application is deciding what functionality to provide to

the users and how to present that functionality, there are some other issues that groupware designers frequently face. In this section we address some of the technical groupware design issues. Many researchers focus mainly on these technical aspects; however, especially in groupware design, the “soft side” is also important. At the end of this chapter we will elaborate on a few of the social and usability groupware design issues.

All groupware applications in the “different place” side of Table 1 are distributed applications that use computer networks for communication. Especially applications in this category that include audio- and videoconferencing have strict requirements regarding network properties such as bandwidth, latency, and jitter. Associated with this, aligning video images and the corresponding audio is a frequently recurring design issue in groupware, known as the lip-synch problem.

When designing distributed groupware, one also has to consider the physical distribution of functionality: what functions are centralized on a server and what is placed locally, i.e., in the groupware clients that people use? Central servers may provide a higher reliability and more computing power, but locally placed functionality avoids network delays. In addition, in distributed groupware, different people may perform actions on the same shared object at almost the same time, whereas network delays are unpredictable. As a consequence, it is difficult to keep the different versions of locally stored replicas of a shared object consistent (e.g., Mauve 2000). To reduce the chance of inconsistencies, objects may be locked by a user. Even providing the “undo” function in this case is not trivial: What do you undo? Your own last action? Or the last action that was performed by any participant? And, what if you wish to undo your action, but somebody else already performed another action on the shared object?

Typically, methods based on operational transformations are applied to address these design issues, with the aim of preserving the intentions of all users.

Another groupware design issue is interoperability (compatibility); both the interoperability of groupware applications of different people (to make sure that people can use groupware from different vendors and still collaborate) and the interoperability of the parts of one groupware application (to make sure you can integrate functionality from different vendors in one groupware application). The latter integration of functionality is often practical from a user perspective, as different tool vendors are good at different aspects: for instance, one vendor may be good at making a groupware environment but not good at making shared CAD software, while another vendor is good only at making shared CAD software.

Deciding on the parts to distinguish in a groupware system, the responsibilities of these parts in terms of the services they provide, as well as their interfaces is an important design challenge. Various groupware reference architectures (as described later in this chapter) have been created to address this issue, but there is no accepted standard yet. Even the way the parts of a groupware system are described has changed; traditionally, the parts were described in terms of software artifacts, although more recently designers describe systems in terms of their behavior: the services a part provides to the groupware users.

Groupware Design Approaches

There are only a few design processes specific for groupware. Dewan (2001) proposed a development process for the design and the evaluation of groupware. He focused on the development of research groupware prototypes and their evaluation using self-studies, lab studies, and field studies. His approach concentrates mainly on the aspect of software design. To complement this, other researchers have added aspects regarding the explicit role of users in the design process, and described approaches on how to deal with typical groupware design processes, in which requirements are shaped as part of the process, for instance based on short iterations in which prototypes are developed and tested.

In groupware design, methods in which users participate in the design process, or are even involved as designers, have become quite prominent (e.g., Grudin, "Groupware and social dynamics," 1994; Slagter, Biemans, and ter Hofte 2001, Teege 2000). Since so-called agile software development approaches and the short development iterations they advocate are in line with the requirements of typical groupware design processes, such methods have also become prominent; for example, all of the approaches mentioned in this section can be classified as agile approaches.

Some methods also stress the importance of adaptability to suit changes in the way people collaborate. When collaborating users can perform these adaptations themselves, a system is said to be tailorable. The issue of designing tailorable groupware will be discussed separately later on in this chapter. Tailoring, as well as end user involvement, has been identified as an important factor in

groupware development processes. Extended STEPS (Wulf and Rohde 1995), OTD (Wulf and Rohde 1995; Wulf et al. 1999), SER (Fischer et al. 2001), and OSDP (Schuemmer 2005; Schuemmer, Lukosch, and Slagter 2006) are design approaches that represent the state of the art in this area.

Extended STEPS

Extended STEPS is an iterative participatory development approach initially proposed by Floyd, Reisin, and Schmidt (1989) and adapted to the context of tailorable collaborative applications by Wulf and Rohde (1995). Extended STEPS combines evolutionary and participative software development with tailoring in use. The authors state that since tailoring can be performed by users, local experts, or support staff, the implementation time for small changes may be reduced significantly, which often appears to be critical to the success of an application.

OTD

The integrated organization and technology development (OTD) process is an evolutionary approach to appropriate group processes and technology to support the processes during system use (Wulf and Rohde 1995; Wulf et al. 1999). OTD is characterized by a parallel development of workplace and organizational and technical systems, the management of (existing) conflicts by discursive means and negotiation and design-time participation of prospective end users. As such, OTD includes organization development, evolutionary models of software development, work psychological analysis, qualification for participation, and tailoring in use.

SER

SER (seeding, evolutionary growth, and reseeding) (Fischer et al. 2001) is a groupware design approach focused around the notion that groupware should be designed as *seeds* that are able to evolve. SER advises a process in which developers and end users collaborate intensively, via a process of informed participation. The core concern of informed participation is to understand how collaborative design processes can be based on participation of the people affected by the decisions reached, the artifacts built, and the technology designed. Informed participation (and its conceptual embedding into the SER model) represents a framework for participatory design that is concerned with:

- The collaborative interactions that take place during the use and evolution of a system rather than just the original design and development of the system.
- Sustaining the usefulness and usability of technology in use over extended periods.

OSDP

The Oregon Software Development Process (OSDP) (Schuemmer 2005; Schuemmer et al. 2006) is based on a series of good practices, formulated as requirements for a groupware-design-process model. To meet these good practices, OSDP distinguishes four main principles:

- Fostering end-user participation
- Pattern-oriented transfer and capturing of design knowledge

- Piecemeal growth via short design and development iterations
- Frequent diagnosis and reflection on working practices and how the application supports the collaboration

An essential part of this development process is the use of patterns. These patterns are used not only as a means to capture and represent design knowledge, but also as a means of communication between end users, designers, and other stakeholders.

Given these different types of use, OSDP distinguishes two types of patterns:

- Low-level patterns targeted at software developers
- High-level patterns targeted at end users

Low-level patterns deal, for example, with class structures, control flow, or network communication.

High-level patterns focus on the system behavior, as it is perceived by end users, and empower end users to tailor their groupware application to meet new or changing requirements. In the extreme, high-level patterns describe how end users can select and compose off-the-shelf components to combine the groupware functionality they need. In that case, end users no longer need the assistance of developers or system administrators in implementing a pattern.

Groupware Architectures

Groupware architectures describe, on a high level of abstraction, the parts of a groupware system (typically in terms of functional building blocks), the relations between these building blocks and the principles surrounding why the decomposition is chosen as it is. In short, a groupware architecture describes the structure of a groupware application and a vision. This section discusses a selection of groupware architectures, to illustrate various decompositions.

CoMeCo

The CoMeCo Groupware Service Architecture by ter Hofte (1998) is a groupware reference model that decomposes groupware services into so-called grouplet service classes. The Groupware Service Architecture is named after the three grouplet service classes it distinguishes:

- *Conference management grouplet services*: These grouplet services provide users with the functionality to manage a set of online conferences, change conference membership, and, for instance, change the set of active media in the conference.
- *Medium grouplet services*: These grouplet services provide users all of the services required to support the interaction related to a single medium. In the CoMeCo Groupware Service Architecture, a medium may be a shared artifact, such as a shared whiteboard, a document, etc. It may also be a communication channel, such as an audioconferencing connection.
- *Coordination grouplet services*: These grouplet services may be applied to active media in a conference. When

applied, they provide a coordination policy that specifies which conference members may or must perform which medium actions at which moment.

As illustrated in Figure 6, CoMeCo defines a conference as a collection of members, media, coordination policies, and subconferences. Media can, for instance, be shared virtual workspaces for indirect communication or conversation channels for direct communication. The CoMeCo Groupware Service Architecture has been implemented in a number of prototypes, including CoCoDoc and Media-Builder. The latter has been professionalized by Lucent Technologies into an application for high-quality audio- and videoconferencing and application sharing. CoMeCo does not specify the actions and interactions that take place as part of units of groupware behavior, nor does it describe the causal relations between units of groupware behavior.

Dewan's Generic Collaborative Architecture

Dewan (1998) has developed a generic collaborative architecture that can be considered a reference model for the internal structure of groupware applications. His architecture describes how collaborative applications can be designed using functional layers. Such functional layers can be shared (i.e., centralized) or replicated. The bottommost layers of the architecture, as depicted in Figure 7, are the workstation layers managing the screen and input devices attached to a workstation. The workstation layers are usually replicated to allow collaborators to use different workstations. The topmost layer in the architecture represents the semantic layer. Unlike the objects in the other layers, the objects in the semantic layer are themselves not an interactor for another object.

Figure 6: CoMeCo groupware service architecture

Figure 7: Dewan's generic collaborative architecture

Design choices regarding the sharing or replication of functional layers influence performance, ease of adaptation, and other properties desired by users and programmers of the application. Specifically, these design choices influence the following aspects of a collaborative application (Dewan 1998):

- *Single-user architecture*: What is the architecture for implementing single-user semantics?
- *Concurrency*: What components of the application can execute concurrently?
- *Distribution*: Which of these components can execute on separate hosts?
- *Versioning/Replication*: Which of these components are replicated?
- *Collaboration awareness*: Which of these components are collaboration-aware—that is, implement collaboration semantics?

Clover Architecture

Similar to Dewan's generic collaborative architecture, the Clover architecture for groupware defines several functional layers to implement groupware. As an extension, the Clover design model specifies at each layer a partitioning into production, communication, and coordination functions (Laurillau and Nigay 2002), as illustrated in Figure 8.

These production, communication, and co-ordination functions have been adopted from the PAC architectural model (Calvary, Coutaz, and Nigay 1997). In the Clover design model, *production functions* denote the functions needed to access and adapt a set of shared information

objects (in Clover, denoted as a *caddy*). The *communication functions* allow for direct communication between the users of Clover. Finally, the *coordination functions* in Clover encompass functions to join and leave sessions, to create, join, or leave a working group, and to enter personal preferences. Note that these coordination functions correspond to conference management services identified in the CoMeCo Groupware Service Architecture, not to the coordination functions identified in that model. The combined Clover production functions and communication functions correspond to the CoMeCo communication functions.

CooPS

The CooPS groupware architecture (Slagter 2004) describes a structuring of synchronous collaborative services. The central principle of the architecture is that groupware applications should be designed in such a way that collaborating end users can select and compose the groupware behavior that matches their specific setting. The architecture provides a structuring of groupware services (i.e., groupware behavior toward collaborating people) on two levels of abstraction: it describes high-level types of units to construct groupware services behavior as well as the more fine-grained atoms to construct them. The first types, in CooPS denoted as groupware service modules (GSMs), are coarse-grained functional building blocks that group functionalities that are typically used together. These building blocks can be selected and composed by collaborating end users to tailor the groupware behavior to their needs and personal preferences. The CooPS groupware architecture distinguishes:

- Awareness building blocks, that support people in the process of launching collaboration (conference-listing GSMs and people-listing GSMs)
- A conference-management building block that provides all services related to started and stopping the conference, group management, and management of which coordination policy applies
- The coordination building block contains all services to actually specify the details of the coordination policy, such as a workflow, and to enforce it
- A communication/collaboration building block contains all services related to one collaboration function (e.g., audioconferencing, instant messaging, sharing computer-aided design drawings). A typical groupware composition includes multiple communication/collaboration building blocks.

Figure 9 illustrates the five main types of GSMs distinguished in the CooPS groupware architecture, which together provide collaborative services to end users.

The figure also illustrates that when zooming in on one individual GSM type, even smaller parts can be distinguished. In CooPS, these atoms are denoted as groupware service module elements (GSMEs). GSMEs are defined to provide one basic groupware service, and form the typical units of design and composition as used by developers.

Figure 8: Clover architecture (FC = functional core)

Figure 9: The CoopS groupware architecture (and zooming in on one GSM)

Component Groupware Platforms and Toolkits

One possible way of creating adaptable groupware is to design these applications out of individual modules that provide a selection of groupware behavior. In that case, the behavior of an application is determined by the set of modules of which it is composed. A groupware application that is composed of such functional modules is denoted as *component groupware*. The following sections introduce various component groupware platforms and toolkits from industry and academia.

COAST

COAST (COoperative Application Systems Toolkit) is a toolkit that offers developers an architecture for cooperative applications and corresponding classes that can be used to implement such applications (Schuckmann, Kirchner, Schuemmer, and Haake 1996). The implementation of the toolkit does not require any specific platform (such as an operating system, user interface management system, or communication channel). User requirements are reflected in the following features:

- A replication mechanism combined with a fully optimistic concurrency control, which enables immediate processing of user actions independent of network latency
- A synchronization mechanism for replicated objects, ensuring fast propagation of other users' actions
- Dynamic sessions, supporting the flexible coupling of shared objects and users

The COAST groupware architecture, as depicted in Figure 10, defines a layered structure of groupware functions. End users can make use of the groupware functions through the user interface (UI) framework and the application user interface. The application user interface layer makes use of an application domain model, which in turn

Figure 10: COAST architecture (UI = user interface)

relies on a shared application framework. The clients of the various cooperating participants in a conference communicate through centralized mediator components, which provide generic mechanisms to transport information, for replication, and to persistently store information.

EVOLVE

The EVOLVE tailoring platform by Stiemerling (2000) applies an implementation architecture for distributed component-based tailorability for computer supported cooperative work (CSCW) applications. This architecture defines an extension of JavaBeans, called FlexiBeans. FlexiBeans solves some important issues that arise when using JavaBeans for groupware (e.g. the fact that JavaBeans has no mechanism to share remote objects as interaction primitives). The EVOLVE platform is based on a client/server architecture: the central server maintains, for example, the repository with components, keeps descriptions of the hierarchical component architectures of the applications, and manages the user accounts.

The EVOLVE architecture, depicted in Figure 11, defines both the client and the server side of a client/server groupware application. On the server side, the run-time control structures contain structural representations, denoted by a *C*, that define what components are combined in what manner into a groupware application. Such component structures can have proxy objects, denoted by a *P*, that reside either on the server or on the various clients. Each component structure can be instantiated several times, resulting in an equivalent proxy structure for each instance structure. During tailoring, the *C* structures are manipulated. All changes are directly broadcast to all instances (i.e., all *P* structures), which apply them to the running groupware application.

DISCIPLE

The DISCIPLE (DIstributed System for Collaborative Information Processing and LEarning) framework enables sharing of arbitrary JavaBeans applications in real-time synchronous group work (Marsic 1999). DISCIPLE uses a generic collaboration bus providing a plug-and-play environment that enables collaboration with applications that may or may not be collaboration aware. The framework

Figure 11: EVOLVE architecture (API = application programming interface)

Figure 12: DISCIPLE architecture

defines a client/server architecture, as depicted in Figure 12, which aims to offer both a toolkit for development of special-purpose collaboration-aware applications and a framework for sharing existing single-user (collaboration transparent) applications. The framework is designed according to a layered architecture that describes, for example, at the client side, a multimodal human-machine interface layer on top of a layer with application logic. The latter layer makes use of the collaboration bus layer, which is the lowest layer. Spanning all layers is the intelligent agents plane, which provides separate knowledge mechanisms. DISCIPLE uses a hybrid form of a toolkit and a platform approach, specific for a component groupware architecture.

Groove

The Groove Workspace by Groove Networks, Inc., is a commercial initiative for component-based peer-to-peer groupware. The peer-to-peer approach minimizes the need for central servers and allocates as much functionality as possible to the systems of the groupware service users. In Groove, each participant in a conference has his or her own replica of the shared virtual workspace. This approach allows the users to fully control the application, while minimizing the dependency on other (economic) parties.

The Groove platform consists of a series of user interface components and a framework. The user interface

components are connected by means of the framework, which provides basic functions. Such basic functions include security, firewall transparency, account and user ID management, and a basic service to synchronize the state of a workspace (described in XML) with the people with whom you are cooperating. The Groove architecture is shown in Figure 13.

Groove users manage and navigate workspaces through a so-called *transceiver*. Groove workspaces contain facilities for instant messaging and may contain multiple Groove tools.

The Groove platform comes with a set of reusable groupware tools that provide frequently needed groupware functions. More information on the Groove Workspace can be found at www.groove.net/products.

GroupKit

GroupKit is an academic groupware toolkit to support developers in creating applications for synchronous, distributed computer-based conferencing (Roseman and Greenberg 1996). GroupKit reduces the implementation complexity through some key features. The run-time infrastructure automatically manages the creation, interconnection, and communication of the distributed processes that comprise conference sessions. A set of programming abstractions allow developers to control the behavior of distributed processes, to take action on state changes, and to share relevant data.

GroupKit uses an architecture in which session management, conference applications and a central registrar are decoupled, as shown in Figure 14. All end users have a replica of the session manager and the used conference applications, while the registrar resides at a central server. GroupKit, created in Tcl/Tk, offers abstractions for multicast remote procedure calls, an event mechanism, and reading and setting environment variables. Furthermore, GroupKit offers a number of multi-user groupware widgets, which can be used by programmers in conference applications to satisfy some user-centered design requirements.

JViews

JViews is a toolkit for constructing view and repository components for multi-view systems (Grundy, Mugridge,

Figure 13: Groove architecture (UI = user interface)

Figure 14: GroupKit architecture

and Hosking 1997; Grundy, Mugridge, Hosking, and Apperley 1998; Grundy and Hosking 2002). A multi-view system permits different, possibly overlapping, views on shared information. These different views may correspond to different end users. Consistency between the different views is maintained by automatically propagating changes to a shared repository and then to all affected views, according to the Model-View-Controller design pattern (logically only one model exists, which is associated with multiple views). JViews includes abstractions for view and repository components. The repository component corresponds to the model component in the Model-View-Controller design pattern (logically, that is; in fact, each user may have an instance of the model). Furthermore, JViews defines intercomponent relationships. The intercomponent relationships are used for data structures, to aggregate components, and to maintain intercomponent and intracomponent consistency.

The JViews groupware architecture, as depicted in Figure 15, defines a groupware client as being composed of three types of components with different responsibilities: collaboration clients (handling shared cursors,

editing, and versioning of shared information objects), coordination components (handling, for instance, locking) and communication components for direct communication between conference participants.

GROUPWARE TAILORABILITY

As frequently stated in groupware design literature, in groupware one size does not fit all: the behavior provided by a groupware application has to match the requirements of the cooperative setting, in particular the task the people perform together. Moreover, the way people collaborate is likely to change over time, which requires a certain dynamic in groupware support for these processes (Bardram 1998; Bentley and Dourish 1995; Fischer et al. 2001; Kahler, Mørch, Stiemerling, and Wulf 2000; Stiemerling 2000; Slagter 2004; Koch and Teege, 1999; Zigurs, Buckland, Connolly, and Wilson 1999).

However, one cannot predict exactly how people will cooperate, and what changes may occur in the course of that cooperation. By investigating the dynamics of real life cooperation, it is possible to identify types of changes that are likely to occur. Based on this, one can derive which aspects of a groupware design have to be flexible in order to accommodate these changes (Bock and Marca 1995).

To achieve a proper match between the task and the technological support, typically denoted as the *task-technology fit*, it is possible to design an *adaptive* application: an application that adapts its own behavior based on the observations it makes regarding the way it is used. An alternative is that of *adaptable* applications. In the case of an adaptable application a human being performs the adaptation. To achieve a task-technology fit in an adaptable system, two means can be distinguished:

1. A good initial selection of groupware behavior by external experts, based on the characteristics of the collaboration "as is" and "to be." This includes the characteristics of the collaborating people, the tasks they perform together, and the context in which the collaboration takes place (e.g., in the office, on the road, or at home).

Figure 15: JViews architecture (UI = user interface; GW = groupware; C/S = client/server; P2P = peer-to-peer)

2. Allowing the collaborating people *themselves* to adapt the behavior of their groupware applications. Such adaptations by end users in the context of system use are denoted as *tailoring*.

Tailoring is defined as the activity of adapting a computer application within the context of its use (Mørch 1997). As such, tailoring is performed by end users, not by programmers.

Tailorability denotes the capacity of a computer application to be tailored. In both situations described above, people select, adjust, and combine the groupware behavior elements that suit their needs. However, the people who perform these operations differ in the two situations described above. In the first one, experts do the adaptations, while in the second one, the end users perform the adaptations. In the latter situation, one cannot assume an expert will be available to assist the end user. So, it is important to select a mechanism to adapt the behavior of groupware applications that is appropriate for experts as well as end users.

As indicated in Figure 16, tailoring is conceptually located between system use and programming: just like programming, it is applied to adapt the behavior of a system. However, the possibilities for adaptations are more limited than when programming. Tailoring is performed in the context of system use, but it is not the primary reason why people use the system: it is only a means, not the objective.

Tailoring is related to *appropriation*, which can be described as a collaborative effort of end users, who perform “appropriation activities” to make sense of the software in their work context. Besides activities to configure the software to fit into the technological, organizational, and individual work context of the users (“tailoring”), there is a larger area of technology-related communication, demonstration, and negotiation activities aimed at establishing a shared understanding of how a software artifact works and what it can contribute to the shared work context. The mutual shaping of the technology and

Figure 16: The relation between programming, tailoring, and use (Biemans and ter Hofte 1999)

organizational contexts resembles an ongoing design process that end users perform largely with no involvement of professional developers (Pipek 2005).

Apart from dynamic requirements, diversity is another driving factor for tailorability. Today, completely custom-built systems are the exception, because it is much more economical to tailor off-the-shelf products to an organization’s specific requirements (Stiemerling 2000). On a smaller scale, the different users in an organization may have different requirements for their technological support, given their specific tasks and personal preferences. From the vendor’s perspective, a tailorable software system promises to reach a larger market segment than a rigid one.

A third reason for tailoring frequently mentioned in CSCW literature results from the so-called *critical mass* problem (Markus 1990; Koch and Teege 1999): some groupware applications can be successful only when many people use the application. This has been found in e-mail, synchronous communication, and calendaring applications (Palen 1998). So, the acceptance of the software by all members of the group, rather than only by

some individuals, is crucial to its success. This is, however, not always easy to achieve, since group members usually have different preferences (such as for a specific text editor), different experiences, and often heterogeneous skills and education (Koch and Teege 1999). Tailoring can help to overcome these differences, as individual group members can adapt the application according to their individual needs and preferences (Oppermann and Simm 1994), while still being able to cooperate.

THE SOFT SIDE OF GROUPWARE

The research field of CSCW, which includes the research into designing groupware, acknowledges that the success of CSCW depends on much more than a good technical design. For instance, insight in the nature of collaboration processes and human-computer interaction are essential as well. This section describes some of these aspects, which are sometimes referred to as “the soft side of groupware.”

Adoption and Acceptance

Robert Metcalf's law states that the “value” or “power” of a network increases in proportion to the square of the number of nodes on the network. Applying this law to groupware, we state that the value of a groupware application increases in proportion to the square of the number of people who use it. Actually, many groupware systems require a critical mass of users before this value reaches the point at which the benefits outweigh the costs. For instance, having a videophone is useless if you are the only one who has it. Two of the most common reasons for failing to achieve critical mass are lack of interoperability and the lack of appropriate individual benefit (Brinck 2006).

Interoperability

In the early 1990s, AT&T and MCI both introduced videophones commercially, but their two systems could not communicate with each other. This lack of interoperability (compatibility) meant that anyone who wanted to buy a videophone had to make sure that everyone they wanted to talk to would buy the same system. Although some de facto standards have emerged, interoperability is essential to allow collaboration with people who use a groupware system by a different vendor. Important standards in the field of groupware are the simple mail transfer protocol (SMTP) for e-mail, the instant messaging and presence protocol (IMPP) for instant messaging, and the session initiation protocol (SIP) and session description protocol (SDP) as well as the ITU-T H.323 standard for audio- and videoconferencing.

Perceived benefit

Even when everyone in the group may benefit, if the choice is made by individuals, the system may not succeed. One example is office calendar systems: if everyone enters all their appointments, then everyone has the benefit of being able to safely schedule around other people's appointments. However, if it is not easy to enter your appointments, then it may be perceived by users as more beneficial not to enter their own appointments, while viewing other people's appointments (Brinck 2006).

This disparity of individual and group benefit is discussed in game theory as the prisoner's dilemma, or the commons problem. To solve this problem, some groups can apply social pressure to enforce groupware use (as in having the boss insist that it be used), but otherwise it is a problem for the groupware designer, who must find a way to make sure the application is perceived as useful for individuals even outside the context of adoption by the full group (Brinck 2006). Although theoretical models can estimate individual and organizational benefits, individuals may not care about the potential benefit of a system; they are likely to use simple heuristics based on usability and perceived benefit to decide whether they will use it.

Trust and Privacy

Over the past few years many researchers have investigated the role of trust in e-business and collaboration in general. These studies confirm that trust is an important requirement for effective and efficient collaboration (Bandow 1998; Daft and Lengel 1986). There are some interesting differences between building trust relations in more traditional settings and in computer-mediated communication. In mediated communication, some of the more subtle signals present in face-to-face communications are missing, as described in media richness theory (Handy 1995). The loss of such information is often considered to increase uncertainty, resulting in lower trust (Shneiderman 2000; Riegelsberger, Sasse, and McCarthy 2005).

However, this view has to be balanced with the fact that technology also offers options to supply information that would otherwise not be easily available (Whittaker 1996). A well-known example is reputation information. Web sites where people exchange goods can, for instance, collect feedback information about people who provide goods from the people who buy it. The aggregate of this information, presented as the reputation of the provider, is available to future buyers. However, gathering reputation feedback poses a challenge, as current buyers derive no direct personal benefit from sharing this information, while at the same time it typically requires an investment from them, for instance by filling in a feedback form.

Related to trust is the issue of privacy. When people use groupware, they frequently need to provide some information about themselves to facilitate the collaboration. For instance, while a shared schedule can be very helpful to coordinate the scheduling of a meeting, it also reveals much information about the people who have entered their appointments in the schedule.

One way to deal with the issue of privacy is to give users as much control as possible over what information is shared with whom and what remains private. Many groupware designs apply the principle of reciprocity: if a user wants information about another user, then they must provide the equivalent information about themselves. For instance, many instant messaging applications only allow you to see the status of someone else if you have granted that person the right to see your status.

Awareness

In addition to explicit communication, such as sending a message or speaking to someone, many group work

situations benefit from implicit communication, such as indirect gestures, information about people's environment (whether their office door is open or closed), or biographical information about people in a conversation (what their job position is and what they had for lunch). Such information, referred to as "awareness information," helps people to establish common ground, to coordinate their activities, and to avoid surprises (Brinck 2006). One of the main research questions when designing groupware is to convey the right and the proper amount of awareness information: What information does one need about others for effective collaboration? It may, for instance, be helpful if I know when the others are available for communication, what they are currently doing, or where they are.

Awareness information can take many forms. In e-mail, information about the time and date of the message or the signature added by the sender provides context for making sense of the message. Instant messaging tools typically provide awareness about whether your contacts are available for communication. Some synchronous, text-based collaboration systems even provide awareness information of another person in typing a message, to subtly coordinate the actions of participants.

Obviously, awareness can be at odds with privacy concerns and, as the last section indicated, it is important to give users control over how much information about themselves is made available to others (Brinck 2006).

CONCLUSION

This chapter characterizes some existing applications for computer-mediated communication, denoted as groupware, and focuses on the design of such groupware applications. The examples of groupware functionality and existing groupware applications illustrate the diversity of the groupware landscape. After depicting this landscape, we have introduced some groupware design approaches. More than generic software design approaches, these approaches focus on the fact that typical groupware design processes are *learning processes*, not just for the prospective users, but also for the designers, who have to build a deep understanding of the collaborative setting to support.

Many collaborative settings turn out to be dynamic: the collaborating people themselves may change, the tasks they perform together may change, or the context in which they perform these tasks may change. These dynamics require flexible groupware solutions, as reflected by the fact that many recent groupware design approaches aim for adaptable groupware application. In fact, some groupware systems are designed according to an architecture that does not just allow developers to adapt the provided functionality, but even allows end users to perform such adaptations. The section on groupware tailorability goes more deeply into such adaptations by end users.

Finally, groupware design processes have a social-technical design: properly supporting collaboration requires not just appropriate technical facilities, but also requires insight in the social aspects around collaboration, such as acceptance, trust, privacy and awareness. From our experience we know that successful introduction of

groupware in a work setting frequently also requires some organizational changes, and at least a deep awareness of the way people collaborate. That brings us to the primary rule of designing groupware: focus on the collaborating people, their working practices, and the services they require from the groupware application to support them in their collaboration.

GLOSSARY

Asynchronous Collaboration: A situation in which the collaborating people do not necessarily work at the same time.

Client/Server Groupware: Groupware applications that make use of a central server, typically as a virtual meeting place, for high availability or for advanced computing and storage capabilities.

Computer Supported Cooperative Work (CSCW): The field of research that investigates the social and technical aspects of computer supported human collaboration in professional settings.

Groupware: Any type of software application designed to support groups of people in communication and collaboration on shared information objects.

Groupware Reference Model: A model that prescribes the parts of a groupware system, the responsibilities of these parts and the way they interact. Groupware reference models act as standards and aim to increase interoperability.

Interoperability: When designing a groupware application out of different parts, one can distinguish two forms of interoperability: interoperability between the parts that form one groupware application (within an application), and interoperability between the groupware applications of different participants. In both cases, interoperability denotes the capacity to (technically) integrate parts or systems from different sources (such as different vendors) into a well-functioning composition. In the case of interoperability between groupware applications, this means that people can work together, even if they use groupware applications from different vendors.

Peer-to-Peer Groupware: Groupware applications that avoid reliance on central servers, but instead use the computing power and storage capabilities of the computers of the collaborating people themselves.

Social-Technical Design: Design processes that focus not only on creating appropriate technical facilities, but also on obtaining insight into and designing for the social aspects around collaboration, such as acceptance, trust, privacy, and awareness.

Synchronous Collaboration: A situation in which the collaborating people work together at the same time.

Tailorability: The ability of a system to be adapted by end users while they are using the system. In the context of this chapter, adaptations may range from changing the layout of the groupware user interface to selecting functionality to collaborate.

Voice over IP (VoIP): A class of collaboration functionality (both in hardware and software) in which the Internet protocol (IP) is used for transmitting audio between collaborating people.

INTRODUCTION

What Is Network Middleware?

Middleware refers to a broad range of software that enables communication or data exchange between network-based applications across networks. Specifically, network middleware enables data exchange by translating data requests and responses between clients and servers. This type of software is often described as “glue” because it connects or integrates business-critical software applications to other applications. By performing some of the tasks that an application would have performed, middleware eliminates the need for an application that is shared by multiple clients to function differently for each different type of client.

Before going in-depth on the technology let's see the difference between a *process* and a *service*. Any software application that runs on a computer is termed a “process.” For example, Figure 1 shows the Windows Task

Manager screen of WINWORD.EXE, a process that indicates that Microsoft Word is being used by the user. These applications are also known as “tasks.”

Software applications that do not require manual intervention are termed “services.” They are started when the computer starts. Figure 2 shows such services.

The DHCP Client is a service that allows the client computer to communicate with the Domain controller and is responsible for obtaining an Internet protocol (IP) address from it when the user logs into the network.

These services run in the background without interfering with the user's interaction with the computer. They are different from XML Web services, which use standard protocols like HTTP and simple object access protocol (SOAP) to communicate.

Middleware Architecture and Services

Middleware typically runs as a separate service and on a separate server from the network operating system, but it may run on the same server. In a simple description of how it functions, middleware sits between two or more applications:

1. to accept requests for access to information or network services
2. to reformat those requests in such a way that the application (on the server) can interpret it
3. to send responses to those requests

For example, when a user requests information from a Web site's database, middleware provides the services for that exchange to occur. As such, it is also considered to be the “plumbing” or utility layer in networks. By promoting standardization and interoperability, middleware makes advanced network applications easier to use. Middleware provides security, identity, and the ability to access information regardless of location—in addition to authentication, authorization, directories, and encryption.

Figure 3 shows a generic middleware infrastructure. This diagram shows middleware acting as an integrator of applications and data and as a provider of secure connectivity and interoperability.

Because it is a general term for any programming that serves to “glue together” or mediate between two separate

Figure 1: WINWORD.EXE

Figure 2: Windows

Figure 3: Generic architecture of middleware operating between the supporting information technology (IT) infrastructure and corporate applications (B2B = business-to-business (B2B); B2C = business-to-consumer; CRM = customer relationship management; ERP = enterprise resource planning; SCM = supply chain management)

and typically already existing programs, the term *middleware* is used to refer to either software or infrastructure. As software, it is the layer between a network and the applications that use it. In addition, middleware is an infrastructure that manages security, access, and information exchange on behalf of applications to make it easier and more secure for people to communicate and collaborate. It can be used to find people or objects (e.g., directory services).

Core and Industry-Specific Middleware Solutions

Business operations—especially enterprise resource planning (ERP), supply chain management (SCM), customer relationship management (CRM), and business-to-business (B2B) and business-to-consumer (B2C) electronic commerce (e-commerce)—depend on secured data transfers between today's networked-based applications.

Middleware programs are also used to provide messaging services so that different applications can communicate. This systematic tying together of disparate applications is known as enterprise application integration (EAI). A common middleware application is to enable programs written for access to a specific database to access other databases.

For end users, middleware makes sharing of network resources transparent and much easier. Moreover, it increases security by protecting against unauthorized or inappropriate use. The problem of security in a distributed environment is too difficult to be solved thoroughly by each individual application. Without middleware, applications would have to provide these services themselves, which could result in competing and incompatible standards—and increase the risk of unauthorized access. Therefore, having the middleware assume this responsibility leads to more robust and consistent solutions. This is done primarily through single sign-on (SSO) technologies. SSO makes it possible for users to enter their credentials only once and to remain authorized within the network until they log off. A widely used SSO technology is Kerberos. SSO and Kerberos are discussed in detail in the following sections.

For company networks or e-commerce operations, middleware plays a pivotal role in connecting enterprise information technology (IT) environments to the Internet. Secure connections are achieved using middleware to control access; that is, only allowing authenticated users, applications, or network end points to connect to an organization's services, applications, and data.

Some of the widely used middleware applications are distributed computing environment, common object request broker architecture (CORBA), and Microsoft's COM/DCOM. A new architecture known as service-oriented architecture (SOA) has become popular. SOA middleware is often deployed as a suite that includes an application server, repository/registry, security, and management tools. SOA is essentially a Web services-based IT infrastructure based around business processes and services instead of siloed, stand-alone applications.

Understanding the Concepts of Middleware

In today's distributed application environment it has become very important for one or more machines in the network to interact with one another, providing information/data needed by the processes running on the machines. To reach this requirement software programs are designed and developed that provide a mechanism to provide these services, these software programs are termed "middleware."

All applications are migrating from the mainframe days to a more distributed, or client/server, environment. Middleware has proved to be a very important piece in the framework to provide communication in a heterogeneous environment. Middleware can act as an abstraction for programming or as infrastructure. These roles are discussed further in detail later.

MIDDLEWARE PROCESSES

As just mentioned, middleware can either act as an abstract program or as an infrastructure. Let's see what this means.

Abstractions in Programming

Programming languages and software systems continuously evolve with levels of abstraction. The abstraction level can be between the platform and the hardware it is running on. Or the abstraction can isolate certain tasks that may be difficult, leaving it for the intermediates to handle. The intermediates can be compilers, load balancers, data allocations, etc. Because of these levels of abstraction, the numbers of errors are reduced during the development of software systems, resulting in huge cost savings in the maintenance of these systems. To aid in the development of these complex and distributed applications, middleware provides a set of abstractions. To understand how middleware platform functions, you must understand the programming model of the middleware. Looking at the programming model, you can determine its limitations, its usability, and its performance in a demanding environment. This understanding and insight will also give you foresight on the evolution of the platform when new technologies are developed and existing technologies are evolved. Figure 4 shows the structure of middleware.

Even though the important part of middleware is programming in abstraction, this is not the only important factor. If the implementation and the supporting system underneath the middleware are not good, the benefit of good abstraction is lost. A few good examples of this

Figure 4: Structure of middleware (RMI = remote method invocation; RPC = remote procedure call; TCP = transmission control protocol; TP = transaction processing; UDP = user datagram protocol)

implementation are Java and the Internet itself. Java is a programming language used to develop software; it keeps the complexity of the underlying system specifications away from the coders. The only interface that a coder interacts with is the Java Virtual Machine (JVM), which is independent of the computer being used. Microsoft has come out with the .NET Framework that also offers these features. With this framework the deployment of code on different environments is easier because it helps standardize the abstractions needed in middleware.

The Internet is a network that needs enhanced abstraction. This enhancement is achieved with the simple object access protocol (SOAP), which is a part of Web services. SOAP is basically a remote procedure call (RPC) wrapped within XML and passed to the HTML page, which is easily transported across the internet. These features and middleware's role as an infrastructure are illustrated Figure 5.

Middleware's Role As Infrastructure

In the prior section, we discussed the middleware's role as an abstraction model in a programming world. As the level of abstraction in the programming area increases, the infrastructure that supports abstractions should grow as well. Each new functionality implemented increases the number of software, which proportionally affects the infrastructure in both size and the depth of complexity.

Figure 5: Middleware as an infrastructure (API = application programming interface; DCE = distributed computing environment; IDL = interface definition language)

Additional software layers require additional layers of abstraction. Another feature of the infrastructure is supporting the implementation of new functionality that will reduce the cost and increase the ease of developing, monitoring, and maintenance. It also handles attributes that are not functional, and hence are left out by models related to data, programming, and coding languages such as efficiency, managing available resources, backup and recovery, etc. The main intent of this infrastructure is to provide a robust platform to develop and run complex distributed systems. Because of this direction, software applications are purchased by single vendors to reduce the complexity and to interact with each other with minimal flaws. The goal is to integrate various platforms and to bring flexibility in configuration.

To summarize, middleware exposes a collection of functional APIs (application programming interfaces) in addition to the ones provided by the operating system and services running on a network. This architecture allows the complex application to perform the following:

- Locate and interact with other applications and services over the network.
- Act independently of the platform and network services
- Remain scalable to ever-evolving software applications without losing functionality

There are different types of middleware available, as described below.

Remote Procedure Call

The remote procedure call (RPC) (Figure 6) allows the application logic to be distributed over the network. The application logic on systems located remotely can be called as if it were located on the local system. RPC can help a programmer in implementing infrastructure for all distributed systems, which would not normally be expected of the programmer. It hides the complexity for distributed procedure calls and supplies interface definition language (IDL) to inform the services. RPC is responsible for creating code required for procedural calls remotely and other aspects of communications.

IDL is limited because RPC is a point-to-point protocol, and hence only two entities can interact at a given time. If more entities are involved, then RPC will consider each call among them as independent of each other even though that is not the situation. There may also be partial failures in the system, and recovering from these can be a complex process. For example, if someone placed an order online for an item, but the inventory was not updated, or someone paid for an order, but nothing was done to reflect this activity, then recovery from these errors would be not be easy. Attempts to avoid such errors through RPC creates an unmanageable situation.

Transactional RPC

To overcome the limitation of basic RPC, there is transactional RPC, which has a concept similar to that of RPC but also has transactional capability (Figure 7). This

Figure 6: Remote Procedure Call

Figure 7: Transactional RPC (OSF = Open Software Foundation)

transactional feature is possible by introducing additional services or run-time supports and language constructs, hence bringing many RPC calls into a unit that maintains atomicity in a database. *Atomicity* means that changes to a database follow an *all-or-nothing* rule. Each transaction is atomic if when one part of the transaction fails, the entire transaction fails. It is critical that the database-management system maintain the atomic nature of transactions regardless of a hardware or software failure.

To make end-to-end transactions with a database it exposes interfaces that use the XA standard, which implements two-phase commit. With this connection type, resources that reside in resource managers that are connected to the region can be recovered. This is possible only with resource managers that support the XA interface.

Systems based on an RPC that supports transaction are TP (transaction processing) monitors, which are explained below.

Transaction Processing Monitors

Transaction processing (TP) technology provides the means to develop an efficient and reliable distributed client/server environment that can run transactional applications. It handles the execution of business logic and rules, updates databases, and keeps transaction systems under control. This technology was created 25 years ago by Atlantic Power and Light for their online support system, which shared information resources and system services with operating systems. This technology is used to manage data, access to the network, security, and processing orders. This is a good alternative in terms of cost as compared with upgrading database systems or system resources. Through application services, the TP monitor acts on various requests made by clients, hence the performance of the system is improved. By transferring transaction logic from the client side, the number of client upgrades is reduced. Because this technology is not dependent on the database architecture, it encourages the business model to be flexible and robust, increasing reusability.

Object Request Broker

Object request broker (ORB) middleware technology enables objects to communicate and exchange data. Since ORB technology allows developers to create applications by consuming different objects created by different vendors, as they talk to each other through ORB, it promotes interoperability in a distributed system. The ORB creates an illusion that the object consumed by the client resides on the local system when it actually may be residing on a remote system or another process. Hence, ORB provides the capability for the object to communicate across the system and across platforms. The ORB concept can be implemented in many ways, like compiled within the clients, as a separate process, or it can be included in the system's operating kernel. There are major technologies based on the ORB concept—Common Object Request Broker Architecture (CORBA), Component Object Model (COM) by Microsoft, and remote method invocation (RMI).

CORBA

The Object Management Group (OMG) came out with a standard, which acts as a base for systems based on

Figure 8: ORB. Source: <http://www.sei.cmu.edu/str/descriptions/orb.html>

Figure 10: OMA. Source: <http://www.sei.cmu.edu/str/descriptions/corba.html>

Figure 9: CORBA. Source: <http://www.iks.inf.ethz.ch/education/ws03/eai/Lecture-2.pdf>

components, that is, CORBA (Figure 9). Vendors use this architecture to develop ORB-based products, which provides the benefits of ORB, such as interoperability across various developing tools and operating systems. In 1988, OMG was created with more than six hundred companies from various spectrums of IT.

CORBA plays a significant role in object management architecture (OMA) that outlines various services needed to develop distributed systems. There is one important distinction between CORBA and OMA—the services that one expects to find in CORBA are actually defined in OMA. Figure 10 shows OMA.

Developing a distributed system is equivalent to using RPC. In this case, the definition of the services to be contacted is exposed by the server using IDL. The IDL compiler compiles the definition to produce a stub on the client side and a skeleton on the server side. A repository is maintained that contains information about the method signatures that can be called by the services. All the communication between the client and the server is done through stub and skeleton, hence removing the

Figure 11: CORBA/Client/Server talk on Internet. Source: <http://www.iks.inf.ethz.ch/education/ws03/eai/Lecture-2.pdf>

dependency of client and server on developing language and the operating system. To ensure that ORB is a universal component architecture, there needs to be ways in which ORBs can talk to each other. CORBA provides a protocol for this—general inter-ORB protocol (GIOP) which defines how the ORBs send and receive calls with each other. Another protocol that converts the GIOP messages into TCP/IP is Internet inter-ORB protocol (IIOP), shown in Figure 11. All these protocols have been superseded by Web services.

Message-Oriented Middleware

Message-oriented middleware (MOM) is client/server architecture that uses synchronous communication between components, which is called as request/response model. In this model, the client component sends a request and waits for a response from the server component. This is similar to RPC, discussed earlier. Figure 12 shows typical client/server calls.

There are some disadvantages in this type of architecture. For interaction between the client component and the server component to be synchronous both need to be available. The client sends in a request and the server component works on it and then responds back to the client with the results. The client has to wait for the server to respond, as shown in Figure 13, which is referred to as *idle time*.

Figure 12: MOM architecture (DBMS = database-management system) (Courtesy of the Swiss Federal Institute of Technology, www.iks.inf.ethz.ch/education/ws03/eai/Lecture-5.pdf)

Figure 13: Idle time (Courtesy of Swiss Federal Institute of Technology, www.iks.inf.ethz.ch/education/ws03/eai/Lecture-5.pdf)

During a client call when the server is not available, CORBA or DCOM will instantiate it, which creates overhead. This connection creates a high risk of failure, and makes it difficult to recognize and react to failures. This architecture is more a one-to-one environment, and is not practical in distributed environments. Maintenance of these sessions is expensive and uses up a lot of the CPU's time. There is a fixed number of sessions available at one particular time, thus limiting the number of simultaneous connections. Connection pooling was introduced to overcome this limitation. The risk with synchronous communication is that if either the client or the server component fails, then the context is missing and resynchronization becomes difficult. Determining the time at which the failure took place will be difficult, and if there was a chain of activities then it will be difficult to find the exact location of the failure.

There are two solutions to overcome the limitations of the client/server model discussed above:

- **Improving Support**—Middleware for the client/server model provides mechanisms to handle problems due to synchronous calls, such as transactional RPC, load balancing, and replication of service; this will ensure that the service on the other system is available for the client if the current server is going down for maintenance.
- **Asynchronous Communication**—In this approach, the client component will send a message, and it will be stored until the server component accesses it. There are two ways of handling this—asynchronous RPC and queues.
- **Asynchronous RPC**—In this case, the client component sends a request to the server component and the control returns to client. The client component has to make a second request to access results from the server component. Figure 14 shows this mechanism.
- **Queues**—In this case, the client interact with server using messages. These messages are persistent by putting them in queues, making the system flexible (Figure 15).

Figure 14: Asynchronous RPC (Courtesy of Swiss Federal Institute of Technology, www.iks.inf.ethz.ch/education/ws03/eai/Lecture-5.pdf)

Figure 15: Queues (Courtesy of Swiss Federal Institute of Technology, www.iks.inf.ethz.ch/education/ws03/eai/Lecture-5.pdf)

Since the queues persist, the messages stored in them are available any time the application(s) start listening to the queues, which makes this a very good choice for a distributed and complex environment.

To facilitate distributed components in communicating with each other using messages and queues, a middleware has been developed called message-oriented middleware (MOM). This architecture moves the standard client/server to a more peer-to-peer communication between components. This allows the client component to send messages to components residing on the server in a distributed environment. In return, the server component sends a response message that contains detail about the execution result. This type of message communication between the distributed components is handled by queues. The messages sent by clients are placed in the queues and remain there until the server components start listening to the queues. Using the queue as a mechanism of communication makes delivery of messages asynchronous, which is the strength of MOM. The queues provide fault tolerance along with overall flexibility. The queues also provide a bridge between heterogeneous environments.

By using queues, the problems faced in the client/server model have been solved. Now that the message is persistent, if the node goes down the message will remain in the queue and is not lost. When the node comes back online, the application listening to the queue will check for messages. The queue can also serve more than one application, hence achieving multiplexing. With the use of queues, the application can merge the following into one transaction: retrieving and processing data from the queue, and then putting the response back into the queue. If anything fails, the queue ensures that consistency is maintained in any scenario.

Because of this asynchronous behavior, the clients can perform other functions until they receive a response from the server. This independence between client and server components creates more scalable architectures or applications. Another MOM strength is that it can provide the same message to a group of client components. The benefit in a workflow environment is that any client knows the status of the task and can take action accordingly.

Although MOM provides features for a real distributed environment, there are disadvantages. It becomes difficult to provide synchronous calls, making it necessary to do them manually. Scalability is provided by MOM, but it becomes complicated because MOM does not have transparent accessibility. Because clients use queues to talk to remote components, their availability for local calls is reduced. Both client and remote components have queue details hard-coded into them, which make them less flexible and less manageable.

Service-Oriented Architecture

Service-oriented architecture (SOA) has gained popularity recently, but this idea has been around since the mid-1980s. Because of limitations or nonavailability of standard APIs or middleware, this concept did not become popular. CORBA and the distributed computing environment were early attempts to bring this concept into use, but there were no significant applications to show the potential of this concept. With the introduction

of Web services, the concept of SOA was given a boost, since the underlying architecture of Web Service unites with the concept perfectly.

Since both SOA and Web services architecture expose the services as an XML-based interface, it makes them in sync with each other. The only way these two differ is how they are implemented. Many of times Web services are implemented as point-to-point, which means that the Web Service cannot be discovered, since it is not public. In the case of SOA, universal description, discovery, and integration (UDDI) contains key information about the Web Service interface and methods to contact it. Because of this, it is easy to discover the Web Service to be consumed by other applications.

Any SOA architecture will include the following

- Service provider
- Service consumer
- Messaging infrastructure

What needs to be implemented in the SOA is the service consumer, the contract between the consumer and the provider of the service. The following figure shows SOA concepts in play.

It can be seen from Figure 16 that the service provider supplies a contract and description of the service to be used. The data model associated with the service is referred to by the service description. The service description can be published using any of the many available methods, such as pull or push. Once the service is discovered it does not mean it accepted the contract or will be called; it merely gives information about the interfaces provided by the service.

There are various advantages that businesses are looking at in SOA. Some are listed below:

- Cost Effectiveness. Since the financial budgets are limited SOA helps in reusing already developed services hence saves time and money for new applications.
- Providing flexibility to adapt ever changing technologies quickly.
- Extending the functionality of the application beyond firewall without compromising on infrastructure security.

MIDDLEWARE SERVICES

Before a subject can be authenticated, it has to be tagged with an identifier—a unique way of naming something. A social security number or personal e-mail address is an identifier because each uniquely names an individual—that is, unless two or more people share an e-mail account. In middleware, identifiers can name anything, including abstract concepts such as certain applications or a certain security clearance. The entity named by the identifier is known as its subject.

The key middleware defense services providing access control are authentication, authorization, directories, application programming interfaces (APIs), and abstraction.

We have seen above how abstraction services in middleware provide defense mechanisms. Below, we will briefly address the others defenses.

Figure 16: SOA CONCEPTS

(Courtesy of Adobe, www.adobe.com/enterprise/pdfs/Services_Oriented_Architecture_from_Adobe.pdf)

Authentication

Authentication is the process of providing a private piece of information or physical token to establish whether a subject is who or what its identifier (e.g., username) claims it is. During authentication, a user or object proves it is the subject of an identifier. This service is generally performed by the middleware layer so that applications above it do not need to have their own authentication mechanism.

Identity is authenticated by the presentation of digital credentials. As explained previously, a user must present credentials to a network to gain access to it. In the case of people, the most common credentials used for confirming identity include:

- Something the subject knows, such as a password
- Something the subject has, such as a USB token, digital ID (certified public/private key), smartcards, or challenge-response mechanisms
- Something the subject is, such as photo identification, fingerprints, or biometrics.

As such, authentication is the validation of a user's electronic identity based on proof provided by that user, typically a unique user id/password pair. If a user cannot be authenticated, then he or she would not be granted access to nonpublic network services.

Authentication is most frequently done by asking a user to enter a username and password. Although there are more secure approaches, passwords are often transmitted through open communication channels. The quality of the authentication depends on the guarantee that can be given that the authentication process was not fraudulent or compromised by a hacker attack, such as correctly guessing a password.

The primary issues to be considered about any authentication system pertain to how secure or strong the

authentication process is. The security of any authentication process depends on several variables, primarily the number of factors used to authenticate a subject. Single-factor authentication, such as using only a password, is much less secure than using a USB token activated by a password, which would be a two-factor authentication.

Figure 17 illustrates and describes the steps involved in authentication in a distributed environment, such as secure Web pages. Several of the concepts illustrated in this figure, e.g., Kerberos, are described in subsequent sections.

Steps

1. User's browser requests the secure page from the local Web server. (Go to step 2.)
2. Local Web server checks: Does user's browser have a cookie? (Go to either step 2A or 2B.)
 - A. Yes. (Go to 2Ai.)
 - i. Cookie is present. Local Web server contacts application for service (AFS) server. (Go to step 2Aii.)
 - ii. Does the cookie content correlate with the AFS file? (Go to step 2Aiia or 2Aiib.)
 - a. Yes.
 - The cookie is valid.
 - The local Web server displays the secure page.
 - b. No.
 - The cookie is invalid. Need a different cookie. (Go to step 2Bii.)
 - B. No. (Go to step 2Bi.)
 - i. Cookie is not present. (Go to step 2Bii.)
 - ii. Local Web server passes the user's browser to the secure Web server. (Go to step 2Biii.)

Figure 17: Distributed authentication steps for Web server access Flowchart model of distributed authentication for secure Web pages. Source: <http://distauth.ucdavis.edu/docs/dachart.html>. (AFS = application for service; DB = database)

- iii. Secure Web server requests login ID and Kerberos password. (Go to step 2Biv.)
- iv. Kerberos database (DB) authentication server decides whether log-in is valid. (Go to step 2Biva or 2Bivb.)
 - a. Yes.
 - Log-in is valid. Secure Web server creates AFS file.
 - Secure Web server generates and sends cookie to browser, then redirects browser to local Web server. (Go to step 2.)
 - Local web server displays the secure page.
 - b. No.
 - Log-in is invalid. Try again. (Go to step 2Biii.)

Authorization and Directories

Once authentication has been performed, more credentials or attributes are needed for a subject before that subject can be given access permissions. Authorization is a process of determining whether to allow a subject access to a specific resource or service or another subject. It is also the process of assigning authenticated subjects the rights to carry out specific operations.

Having only one valid identifier does not provide enough information about a subject. Although an authenticated identity may be sufficient for some purposes, it is often important to acquire more information, such as preferences, e-mail aliases, electronic credentials, etc. Identifiers become far more powerful when they are combined with a technology known as directories. Along with its many other uses, a directory links an identifier with other attributes about a common subject.

A directory stores and regulates permissions, such as viewing files. Directories are, in effect, databases composed of many sets of information with a similar format. A set of information is generally called an “entry,” and a piece of information within an entity is called an “attribute.” A primary function of a directory is to look up a given attribute from a given entry, such as a user’s read or write privileges for a specific object (e.g., payroll file). Because directories make information available, access to them must also be adequately protected. Access controls can be set to regulate who can read or update specific directory fields.

The two major technical components of a middleware implementation are client software and enterprise middleware servers that provide authentication and directories. The client side does not require much work because most middleware functions can be performed by existing programs, such as Web browsers and e-mail clients. In contrast, the server side needs to perform many new services. The middleware system must provide an effective and secure layer for communication between client and server. The major client-side technological challenge is establishing the authentication system. Although these systems can be built around passwords, public keys, smart cards, or other schemes, these must be available on every machine that a user will want to use to authenticate to the middleware server.

Application Programming Interfaces

Application programming interfaces (APIs) exist for (almost) all middleware products and establish the interface with which clients (applications) request services of the servers. In other words, APIs are part of all types of middleware, not a separate type. APIs provide for data sharing across different platforms. Specifically, an API is a set of standards and protocols by which a software application can be accessed by other software, or is used for communication between application programs. APIs enable the exchange of messages or data between two or more software applications. The API must exist before a program can be called by an external program and before it can send a response to an external program.

There are several types of APIs that enable data sharing between different software applications on single or distributed platforms. Those APIs include:

1. *Remote procedure calls* (RPCs): These are protocols that provide high-level communications. An RPC implements a logical client-to-server communications system specifically for network applications.
2. *Standard query language* (SQL): SQL is an American National Standards Institute (ANSI) standard computer language for accessing and manipulating databases.
3. *File transfer*: Transporting or sharing files between remote machines.
4. *Message delivery*: Reliable message delivery ensures that Web services architecture, protocols, and interfaces deliver secure, interoperable, transactional, and robust solutions (IBM 2003).

GLOSSARY

Access: Refers to the tasks carried out on an object, such as read, write, modify, delete, etc.

Access Control: Only authorized (or intended) users can gain access to a network or application. Users have only the level of access, or least privilege, needed to accomplish authorized tasks.

API: A set of standards and protocols by which a software application can be accessed by other software, or for communication between application programs.

Application Communication Middleware: Middleware used to communicate between applications, software services, and components.

Application Communication Middleware Architecture: Facilitates and simplifies the communication between diverse, distributed applications.

Authentication: The process of providing a private piece of information or token to establish whether a subject is who or what its identifier (e.g., username) claims it is.

Authorization: The process of determining whether to allow a subject access to a specific resource service or another subject.

Availability: User access to data files or applications that are stored on networked computers. Information and systems are protected against disruption.

Certificate Authority (CA): An entity that issues digital certificates and vouches for the binding between the data items in a certificate.

CIA Triad: Refers to confidentiality, integrity, and availability of information and computing resources.

Cipher Text: Text that is unreadable by humans, such as encrypted text.

Common Object Request Broker Architecture (CORBA): An architecture for creating, distributing, and managing distributed program objects in a network.

Confidentiality: Sensitive information is protected against disclosure.

Distributed Component Object Model (DCOM): Microsoft’s proprietary distributed object architecture, which it developed instead of adhering to CORBA.

Encryption: The process of changing a message (plaintext) into meaningless data (cipher text).

Enterprise Application Integration: The systematic tying together of disparate enterprise applications.

Integrity: Information and systems are protected against unauthorized modification.

Kerberos: A ticket-based authentication protocol based on symmetric key cryptography.

Kerberos ticket: A certificate issued by an authentication server, encrypted using the server key.

Message-Oriented Middleware (MOM): Application communication middleware that sends messages between software components. Applications using MOM can be deployed on multiple platforms using multiple programming languages.

Middleware: Software and APIs that act as intermediaries among application programs and services, such as gateway software between LAN-based database servers and mainframe databases. This software layer provides application, component, and data access communication.

Object: The data, service, or application that is being accessed by a subject.

Object Request Broker (ORB): In a network of clients/servers on different computers, a client program (an object) can request services from a server program or object without having to understand where the server is in a distributed network or what the interface to the server program looks like.

Open: Unprotected, such as an open network.

Packet: A collection of data transmitted as a bundle across a network connection.

Packet Switching: The process of routing and transferring packets of data via a network.

Plaintext: A message in human-readable form.

Platform: A combination of computer hardware and operating system software.

Portability: The capability to move software across different platforms.

Principal: Either a subject or an object whose identity can be verified (e.g., a workstation user or a network server)

Private key: The key that a communicating party holds privately and uses for decryption or completion of a key exchange.

Protocol: A set of rules for communication, or rules for managing the network, transferring data, and synchronizing the states of network components. Protocols enable independent technology components to communicate with each other.

Public Key: The key that a communicating party sends publicly.

Server: A computer that provides shared services to computer workstations over a network, e.g., file server, print server, mail server. In TCP/IP, a server accepts and responds to the requests of a remote system, called a “client.”

Single Sign-on (SSO) Technology: This technology makes it possible for users to enter their credentials only once and to remain authorized within the network until they log off.

Subject: A person (user) or application that requests access to data, a service, application, etc.

Web Services Security (WS-Security): Provides a mechanism for associating security tokens with messages, thus improving protection through message integrity, message confidentiality, and single message authentication.

FURTHER READING

The importance of middleware is increasing. Middleware applications are ever-evolving layers of network and data services. These services reside between the network and more traditional applications. Their role is to manage security, access and information exchange, and the sharing of distributed resources, such as computers, data, and networks. Despite its security features, middleware has become the target of attack. A case in point—Intruders penetrated servers hosting GNOME, an open-source project offering interfaces and development tools to Linux users. This attack has demonstrated that intruders depend not only on vulnerabilities within operating systems, but also increasingly on applications, databases, Web servers, and middleware (Franklin 2004).

INTRODUCTION

The Grid concepts provide a distributed infrastructure for dynamic resource sharing and problem solving across multiple institutional boundaries. It effectively provides a virtualized wide-area distributed system that associates the underlying resources with abstract service interfaces. The Grid concepts and ideas have moved from the world of joining high-performance computing (HPC) systems together to generalized systems based on a service-oriented architecture that can provide infrastructure for a range of applications. At one end of the application spectrum are simple applications that use a client/server paradigm; but these can grow increasingly complex, for example where a workflow system may need to use a sophisticated pipeline of services to fulfil its needs. The infrastructure can support HPC for computationally or data intensive grand challenge applications, or it can provide high-throughput systems that need to spawn hundreds of thousands of tasks in parameter sweeps. The Grid infrastructure is now increasingly being used for new applications too, such as sensor networks, which may contain tens of thousands of sensors.

The aim of this chapter is to provide a brief history of the derivation of Grid concepts and a chronology of the Grid from its early days, when it was used to link HPC facilities in the United States, through today, where it provides a Web Services-based infrastructure for an increasing number of distributed applications. For clarity of understanding, this chapter also includes a definition of what is generally accepted to be a Grid and a discussion of what motivated developers to move away from the earlier procedural interfaces to the service-oriented architectures that are now being advocated. The second half of this chapter includes an extensive, but brief, over-

view of the nine currently available instantiations of Grid infrastructure that are based on either just Web Services, or the Web Services Resource Framework (WSRF).

A DEFINITION OF THE GRID

Currently, there appears to be some confusion about exactly what constitutes a Grid and what are its pertinent features. The reason for this confusion is caused by excessive use and overloading of the term *Grid*, so that today everything from SETI@home to a LAN-based cluster are referred to as a Grid. Foster and Kesselman (1998) provided an initial definition: "A computational Grid is a hardware and software infrastructure that provides dependable, consistent, pervasive, and inexpensive access to high-end computational capabilities." This particular definition stems from the earlier roots of the Grid when it was focused on connecting together high-performance facilities at various U.S. laboratories and universities.

Since this early definition, there have been a number of additional attempts to define a Grid succinctly. In 2001, Foster, Kesselman, and Tuecke refined their definition of a Grid to "coordinated resource sharing and problem solving in dynamic, multi-institutional virtual organizations." This latest definition is the one most commonly used today to abstractly define a Grid today.

Foster (2002) has also produced a checklist that can be used to help understand exactly what can be identified as a Grid system. He suggested that the checklist should have three parts to it. The first part to check off is that there is coordinated resource sharing with no centralized point of control and that the users reside within different administrative domains. If this is not true, it is probably not a Grid system. The second part to check off

is the use of standard, open, general-purpose protocols and interfaces. If this is not the case, it is unlikely that system components will be able to communicate or interoperate, and it is likely that we are dealing with an application-specific system, and not the Grid. The final part to check off is that of delivering nontrivial qualities of service. Here we are considering how the components that make up a Grid can be used in a coordinated way to deliver combined services, which are appreciably greater than the sum of the individual components. These services may be associated with throughput, response time, mean time between failure, security, or many other non-functional facets.

Overall, the Grid is about resource sharing; this includes computers, storage, sensors, and networks. Sharing is obviously always conditional and based on factors such as trust, resource-based policies, negotiation, and how payment should be considered. The Grid also includes co-ordinated problem solving, which is beyond a simple client/server paradigm, in which we may be interested in combinations of distributed data analysis, computation, and collaboration. The Grid also involves dynamic, multi-institutional virtual organizations (VOs), where these new communities overlay classical organizational structures, and these organizations may be large or small, static or dynamic. The European-funded Enabling Grids for E-science (EGEE) project, which aims to build on recent advances in Grid technologies to develop a service-oriented infrastructure, is a good example of where VOs are being used in practice.

The following items cannot be considered a Grid: A PC cluster, a network-attached storage device, a desktop PC, a scientific instrument, a network. Each might be an important component of a Grid, but by itself, it does not constitute a Grid. In addition, systems like SETI@home, distributed.net, and folding@home are wide-area distributed systems, but not part of the Grid.

THE EVOLUTION OF THE GRID

Introduction

The early Grid efforts started as projects to link supercomputing sites; this was known, at the time as “metacomputing.” The origin of the term is believed to have been the CASA project (Gigabit Testbed Initiative 1996), one of several U.S. Gigabit testbeds around in 1989. Larry Smarr, the former Director of the National Center for Supercomputing Applications, is generally accredited with popularizing the term thereafter (Catlett and Smarr, 1992). The original metacomputing or Grid environments emerged in the early to mid-1990s. Typically, the objective of these early projects was to provide computational resources to a range of high-performance applications.

Two projects (Baker and Fox, 1999) in the vanguard of this type of technology were FAFNER and I-WAY. FAFNER was a Web-based system that aimed to address the RSA (Rivest, Shamir, and Adleman) Factoring Challenge, which was capable of executing on any workstation with more than 4 Mbytes of memory. Whereas, I-WAY provided a means of unifying the resources of large U.S. supercomputing centers via specialized software.

These projects differed in many ways, but were in the forefront of projects of their type, and both had to overcome a number of obstacles, including communications, resource management, and the manipulation of remote data, to be able to work efficiently and effectively.

FAFNER

The effectiveness of public key cryptosystems depends on the intractability, both computational and theoretical, of solving certain mathematical problems, for example integer factorization. Public and private keys in such systems are mathematically related, so their private key can only decrypt a message encrypted with a recipient’s public key. To find a private key from a user’s public key is computationally very time consuming to solve, but usually faster than trying all possible keys by brute force.

The use of this type of cryptographic technology has led to integer factorization becoming an active research area. To keep abreast of the state-of-the-art in factoring, RSA Data Security initiated the RSA Factoring Challenge in March 1991. The Factoring Challenge offers a testbed for factoring implementations and provides one of the largest collections of factoring results from many different experts worldwide.

Because factoring is computationally expensive, parallel factoring algorithms have been developed. With these parallel algorithms, factoring can be distributed over a network of computational resources; the algorithms are typically trivially parallel and require no communications after the initial set-up. This type of set-up means that it is possible that many contributors can provide a small part of a larger factoring effort. Early efforts relied on e-mail to distribute and receive factoring code and information.

In 1995, a consortium led by Bellcore Labs., Syracuse University, and Co-Operating Systems started a project of factoring via the Web, known as FAFNER. This project was set up to factor RSA130 using a new numerical technique called the Number Field Sieve (NFS) factoring method using computational Web servers. The consortium produced a Web-based system that interfaced to the NFS executable program.

With this system, a contributor used a Web form to invoke server-side common gateway interface (CGI) scripts written in Perl. Contributors downloaded and built a sieving software daemon, which became their Web client using HTTP GET/POST to get and send the resulting relations from and to a CGI script on the originating Web server. Three factors combined to make this approach succeed (Baker and Fox 1999):

1. The NFS implementation allowed even a workstation with only 4 Mbytes to perform useful work using a small bounds and sieve algorithm.
2. FAFNER supported anonymous registration—users could contribute their hardware resources to the sieving effort without revealing their identity to anyone other than the local server administrator.
3. A consortium of sites was recruited to run the CGI script package locally, forming a hierarchical network

of RSA130 Web servers, which reduced the potential administration bottleneck and allowed sieving to proceed around the clock with minimal human intervention.

The FAFNER project won an award in the TeraFlop challenge at Super Computing 95 (SC95) in San Diego. It paved the way for a wave of Web-based metacomputing projects.

I-WAY

The Information Wide Area Year (I-WAY) project (Foster, Geisler, Nickless, Smith, and Tuecke 1998) was an experimental network linking high-performance computers and visualization systems together. The I-WAY project was conceived in early 1995 to integrate existing high-bandwidth networks with telephone systems. The virtual environments, datasets, and computers used resided at seventeen different U.S. sites and were connected by ten networks of varying bandwidths and protocols, using different routing and switching technologies.

The project used an Asynchronous Transfer Mode (ATM) network, which at the time was an emerging standard that provided the wide-area backbone for various experimental networking activities at SC95. The network supported both ATM and TCP/IP over ATM.

To standardize the I-WAY software interface and management, each site installed a point-of-presence (I-POP) server to act as their gateway to the I-WAY. The I-POP servers were UNIX workstations configured uniformly with a standard software environment called I-Soft. The I-POP server provided uniform authentication, resource reservation, process creation, and communication functions across I-WAY resources. Each I-POP server was accessible via the Internet and operated within its site's firewall. It also had an ATM interface that allowed monitoring and potential management of the site's ATM switch.

The project included a resource scheduler known as the computational resource broker (CRB), which consisted of user-to-CRB and CRB-to-local scheduler protocols. The CRB implementation was set up in terms of a single central scheduler and multiple local scheduler daemons—one per I-POP server. The central scheduler maintained queues of jobs and tables representing the state of local machines, allocating jobs to machines and maintaining state information on the AFS file system.

Security was a major feature of the project, and emphasis was put on providing a uniform authentication environment. Authentication to I-POPs was handled by using a telnet client modified to use Kerberos. In addition, the CRB acted as an authentication proxy, performing subsequent authentication to resources on a user's behalf.

To support user-level tools, a low-level communications library, Nexus was adapted to execute in the I-WAY environment. Nexus supported automatic configuration mechanisms that enabled it to choose the appropriate configuration depending on the technology being used—for example, communications via TCP/IP or AAL5 (the ATM adaptation layer for framed traffic) when using

the Internet or ATM. The MPICH library (a portable implementation of the Message Passing Interface (MPI) message passing standard) and CAVEcomm (networking for the CAVE virtual reality system) were also extended to use Nexus.

The I-WAY project was application-driven and defined several types of applications, including distributed supercomputing, access to remote resources, and virtual reality. The I-WAY project was demonstrated at SC95 in San Diego. The I-POP servers were shown to simplify the configuration, use, and management of this type of wide area testbed. I-Soft, the software that was used by the I-WAY project was a success in terms that most applications ran, most of the time. More importantly, the experiences and software developed as part of the project fed into the Globus project, which is discussed below.

A Summary of Early Experiences

Both FAFNER and I-WAY were environments that attempted to integrate resources from opposite ends of the computing spectrum. FAFNER was a system that worked on any platform with a Web server, whereas I-WAY unified the resources at multiple supercomputing centers.

The two projects also differed in the types of applications that could utilize their environments. FAFNER was tailored to a particular factoring application that was in itself trivially parallel and was not dependent on a fast interconnect. I-WAY, on the other hand, was designed to cope with a range of diverse high-performance applications that typically needed a fast interconnect and powerful resources. Both projects, in their way, lacked scalability. For example, FAFNER was dependent on a lot of human intervention to distribute and collect sieving results, and I-WAY was limited by the design of components that made up I-POP and I-Soft.

FAFNER lacked a number of features that would now be considered obvious. For example, every client had to compile, link, and run a FAFNER daemon in order to contribute to the factoring exercise. FAFNER was really a means of task farming a large number of fine-grained computations. Individual tasks were unable to communicate with one another or with their parent Web server. Likewise, I-WAY had a number of features that would today seem inappropriate. The installation of an I-POP platform made it easier to set up I-WAY services in a uniform manner, but it meant that each site needed to be individually set up to participate. In addition, the I-POP platform and server created one, of many, single points of failure in the design of the I-WAY. Even though this was not reported to be a problem, the failure of an I-POP would mean that a site would drop out of the I-WAY environment.

Notwithstanding the aforementioned features, both FAFNER and I-WAY were both innovative and successful. Each project was in the vanguard of metacomputing and helped pave the way for many subsequent projects. FAFNER was the forerunner of the likes of SETI@home and Distributed.Net, and I-WAY for Globus and Legion.

GRID CONCEPTS AND COMPONENTS

Introduction

A Grid infrastructure will consist of all manner of networked resources, ranging from computers and mass storage devices to databases and special scientific instruments. The core features provided by the fabric of the Grid are:

- Some sort of administrative hierarchy and integration needs to exist to allow a Grid environment to be divided up to cope with a potentially global extent. This component will allow administrative information flow between groups, centers and organizations, so administrative boundaries are hidden, allowing individuals and resources to join, utilize, and leave what are now known as virtual organizations (Wikipedia, 2007).
- Communication services are required to provide Grid applications with a range of transport protocols, ranging from reliable point-to-point to unreliable multicast. The communications infrastructure needs to support protocols that are used for bulk-data transport, streaming data, group communications, and those used by distributed objects.
- A Grid is a dynamic environment in which the location and type of services available are constantly changing. The resources and services must be accessible to any process in the system, without regard to the relative location of the resource or user. It is necessary to provide a rich information environment in which services, resources, and users can publish, search for, and find the end points of interest. Information services provide the mechanisms for registering and obtaining information about the structure, resources, services, status, and nature of the environment.
- Any distributed system needs a range of security services to provide authorization, authentication, confidentiality, and integrity. Security within a Grid environment is a complex issue requiring diverse resources autonomously administered to interact in a manner that does not impact the usability of the resources or introduce security holes/gaps in individual systems or environments as a whole.
- The management of processor time, memory, network, storage, and other components in a distributed system is clearly important. The overall aim is the efficient and effective scheduling of the applications that need to utilize the available resources in the distributed environment. It is important in a Grid that a resource management and scheduling service can interact with the systems that may be installed locally, such as Condor, Load Sharing Facility or Sun's Grid Engine.

These core feature or components are provided, in some manner, by each instantiation of Grid middleware. These components are discussed further in the section on Grid Instantiations below.

The Open Grid Services Architecture

Many changes have occurred since Grid software first appeared, not the least of these has been the increasing

Figure 1: The Open Grid Services Architecture

involvement of commerce and industry as the Grid's potential has started to be realized. The effect of commercial involvement has driven the evolution of the software that supports Grid environments away from its academic/research roots toward industrial quality. This interaction has had an impact on the architecture of the Grid's infrastructure, as well as the associated protocols and standards. The most profound change has been the adoption of Web Services to underpin the infrastructure that supports the Grid.

In June 2002 (Foster, Kesselman, Nick, and Tuecke 2002), the Open Grid Services Architecture (OGSA), developed by the Global Grid Forum's (GGF's) OGSA Working Group OGSA v1.0 (Foster et al. 2004), emerged as a draft specification that aimed to define a common, standard, and open architecture (Figure 1) for Grid-based applications.

OGSA can be seen as the blueprint for the Grid's architecture. OGSA aims to standardize almost all the services that a Grid application may use by defining service interfaces and identifying the protocols for invoking these services. It defines a set of fundamental services—for example, job and resource management services, communications, and security. The interfaces, semantics, and interactions of these services are being standardized by the GGF working groups. OGSA specifies a service-oriented architecture (SOA) for the Grid as a set of distributed computing patterns that are realized using Web Services.

In March 2004, OGSA was declared the Open Grid Forum's (OGF) flagship architecture. Instantiations of OGSA itself depend on emerging specifications and implementations. OGSA plays the coordinating role for the efforts of working groups within the OGF and the other organizations that are participating in developing standards for the Grid. It identifies the requirements for e-Business and e-Science applications in a Grid environment, while the technical details are left to the various working groups.

OGSA extends Web services by introducing a number of interfaces and conventions. Key to OGSA are its services, which are Web Services with improved characteristics due to:

- The dynamic and potentially transient nature of a Grid environment, where service instances may come and go as tasks are dispatched, as resources are configured and provisioned, or as the system's state changes. Consequently, services need interfaces to manage their creation, destruction, and life cycle management.
- Coping with the dynamic and transient nature means that service state is needed, which comes in the form of attributes and associated data. For this purpose, Web services were extended to support state data associated with Grid-based services.
- Providing clients with the ability to register their interest in services so that when there is a change in that service, clients are notified.

The first instantiation of OGSA was the Open Grid Services Infrastructure specification version 1.0 (OGSI), released in July 2003 (Tuecke et al. 2003). OGSI defined a set of principles and extensions on the use of the Web Services Definition Language (WSDL) and XML Schema to enable stateful Web Services.

OGSI introduced the term *Grid service*, which was an enhanced Web service that implemented the GridService portType. This term is now deprecated (OGSA Glossary). In OGSI, a Grid service was created to manage each new piece of state and provided a standard set of mechanisms for managing the state of a service. Several problems were identified with OGSI, some were political and others technical (Tuecke et al. 2003; Czajkowski et al. 2004), these are described next:

- It was thought that the OGSI specification was too large and contained too much for one specification.
- OGSI did not work well with current Web Services tooling. OGSI was not a pure subset of Web services and required a modification to the standard WSDL, called the Grid-WSDL (or GWSDL). This meant that commercial and noncommercial WSDL tools would need to be extended to parse and process the WSDL for these Grid services.
- OGSI was seen as too object-oriented, even though many other Web services systems have object-oriented implementations. OGSI used concepts from object-oriented programming, such as statefulness and the factory model, which was used to create Grid service instances, thus supporting transient, potentially short-lived services.

The Motivation behind WSRF

The original Grid systems, such as the Globus Toolkit versions 1 and 2, focused on the sharing of physical resources via procedural software frameworks. These systems, however, did not fit the emerging needs of the distributed computing community. It was argued that enterprise information technology (IT) infrastructures and multi-organizational Grid systems are concerned with the creation, management, and application of dynamic ensembles of resources and services (Czajkowski et al. 2004). It was believed that a service-oriented view of architecture was more fitting for the long-term viability of

the software needed to bind together distributed Grid and IT infrastructures. The goal of Service-Oriented Architectures (SOA) is to lessen the problems of heterogeneity, interoperability, and ever-changing system requirements. A SOA provides a platform for building application and other services, which are loosely coupled, location-transparent, and protocol-independent.

In software terms, a service is generally implemented as a coarse-grained, discoverable entity that exists as a single instance and interacts with applications and other services through a loosely coupled, message-based communication model. An important aspect of the Grid was the need to provide stateful resources. Historically, Grid systems provided their clients with access to some view of their internal state. Grid systems would typically allow a client to access stateful data, which may refer to CPU use, memory consumption, or job reservation information.

With Web Services, an operation's execution is available at an end point address. A service is defined in terms of the operations it implements, and an operation is defined in terms of a message exchange, such as SOAP or WSDL. The lifecycle of a Web service is described in terms of its deployment and can be found via a discovery process. HTTP is stateless, so when Web services came along, they also remained stateless. The only way to introduce state (or security for that matter) was to insert, piggy-back style, a token or other identifier into the message envelopes.

WSRF provides a set of operations that Web Services may implement to become stateful. A client can communicate with a resource, allowing data to be stored and retrieved. Foster et al. (OGSI to WSRF. 2004) have produced a technical document (Czajkowski et al. 2004) discussing the differences between OGSI and WSRF. WSRF has a standard approach to extend Web Services. It is based on a set of different standard/recommended WS-* specifications:

- WS-Resource
- WS-ResourceProperties (WSRF-RP)
- WS-ResourceLifetime (WSRF-RL)
- WS-ServiceGroup (WSRF-SG)
- WS-BaseFaults (WSRF-BF)
- WS-Addressing
- WS-Notification

WSRF is itself extendable through other WS-* specifications like WS-Policy, WS-Security, WS-Transaction, and WS-Coordination.

WSRF Specifications

WS-ResourceProperties (WSRF-RP)

A WS-Resource has zero or more properties expressible in XML, representing a view on the WS-Resource's state. Without WSRF, clients of a Web service can access and manipulate its state using an application-specific interface. The properties of a WS-Resource are modeled as XML elements in the resource properties document. To allow the generic use of resource properties, WSRF defines a number of

standard operations that a WS-Resource may support. The operation `GetResourceProperty` is mandatory, whereas all the other operations are optional. `WS-ResourceProperties` optionally uses `WS-Notification` to allow clients to request notification of changes made to the values of one or more resource properties.

WS-ResourceLifetime (WS-RL)

The `WS-ResourceLifetime` specification standardizes the means by which a WS-Resource can be monitored, manipulated, and destroyed. The specification does not detail the means by which a resource is created, but can specify that it should be immediately destroyed, its termination time, or changes to the termination time. `WS-ResourceLifetime` does not mandate that the resource be destroyed immediately after the scheduled destruction time; however, the client must not assume that the resource will be available after that time.

WS-ServiceGroup (WS-SG)

The `WS-ServiceGroup` specification defines a means of representing and managing heterogeneous, by-reference, collections of Web services. This specification can be used to organize collections of WS-Resources—for example, to aggregate and build services that can perform collective operations on a set of WS-Resources. The `WS-ServiceGroup` specification can express group membership rules, constraints, and classifications using the resource property model from `WS-ResourceProperties`. Groups can be defined as a collection of members that meet some constraints as expressed through resource properties.

A service group is a WS-Resource, and the members of the group are modeled as `Entry` properties in the resource property document, together with various membership constraints that a group can impose. In addition, the member entries (not the member services) are also WS-Resources (referenced from the `Entry` properties), which may use `WS-ResourceLifetime` methods for scheduling the removal of a member service from the group (or removing it immediately).

To add members to a group, `WS-ServiceGroup` defines a single operation called `Add`, which is used by specifying the member service reference and the initial termination time for the membership. `WS-ServiceGroup` also provides an optional means to notify a service group about a modification using `WS-Notification`.

WS-BaseFaults (WS-BF)

`WS-BaseFaults` defines an XML Schema for base faults, which are defined in the XML Base Faults namespace, along with rules for how this base fault type is used and extended by Web services.

WS-Addressing (WSA)

`WS-Addressing` provides a mechanism to place the target, source, and other important address information directly within a Web Services message. In short, `WS-Addressing` decouples address information from any specific transport protocol. `WS-Addressing` provides a mechanism called an end-point reference for addressing entities managed by a service. The end-point reference provides a

standard XML element that allows a structured approach to encoding fine-grained addressing. The combination of fine-grained addressing coupled with the transport-neutral encoding of the message source and destination means that Web Services' messages can be sent across a range of transports and through intermediaries. `WS-Addressing` also lets a sender indicate where a response should go in a transport-independent manner.

WS-Notification

`WS-Notification` is a family of documents including three specifications: `WS-BaseNotification`, `WS-BrokeredNotification`, and `WS-Topics`.

`WS-BaseNotification` defines the Web services interfaces for `NotificationProducers` and `NotificationConsumers`. The specification includes the standard message exchanges to be implemented by service providers that wish to act in these roles, along with operational requirements expected of them.

`WS-BrokeredNotification` defines the Web services interface for the `NotificationBroker`, which is an intermediary that, among other things, allows the publication of messages from entities that are not themselves service providers. The specification includes standard message exchanges to be implemented by `NotificationBroker` service providers along with operational requirements expected of service providers and requestors that participate in brokered notifications.

`WS-Topics` defines a mechanism to organize and categorize items of interest for subscription known as "topics." These are used in conjunction with the notification mechanisms defined in `WS-BaseNotification`. `WS-Topics` defines three topic expression dialects that can be used as subscription expressions in subscribe request messages and other parts of the `WS-Notification` system. It further specifies an XML model for describing metadata associated with topics.

GRID INSTANTIATIONS

Since the mid-1990s, a number of international groups have been developing software to address the concepts of a Grid environment. Today, there is an increasing number of instantiations of Grid software that conform to OGSA and implement the WSRF specifications. This section briefly describes some of the more popular systems in terms of their layout/architecture and the services that they use.

The Globus Toolkit 4 (GT4)

The Globus Toolkit is developed by the Globus Alliance. It includes a number of services, most of which are implemented on top of WSRF, although some are not.

The Globus Toolkit 4 software components are shown (Figure 2.) These components are divided into five categories: Security, Data Management, Execution Management,

Figure 2: The Globus Toolkit Version 4 (Foster 2005)

Information Services, and the Common Run-time. Note that even though GT4 focuses on Web services, the toolkit also includes components that are based on earlier services. For example, the GridFTP component uses a non-WS protocol, which started as one used by the Globus toolkit, but later became a GGF specification.

GT4 includes the following components (shown via a layered view in Figure 2):

- The common run-time components provide a set of libraries and tools, which are needed to build all Globus services.
- The security components are based on the Grid Security Infrastructure (GSI), which allows secure authentication and communication over an open network.
- The data management components allow the management of large sets of data in a Globus-based virtual organization.
- The information services, more commonly known as the monitoring and discovery service (MDS), includes a set of components to discover and monitor resources in a virtual organization.
- The execution management components deal with the initiation, monitoring, management, scheduling, and coordination of executable programs.

UNICORE

The Uniform Interface to Computing Resources project started in August 1997. The aim of the project was to seamlessly and securely join together a number of German supercomputing centers virtually without changing their existing procedures. The UNICORE consortium consisted of developers, centers, users, and vendors. The initial UNICORE system had a security architecture based on X.509 certificates, a graphical user interface (GUI) based on Java Applets and a Web browser, and a central job scheduler that used Codine from Genias (now Sun's Grid Engine).

UNICORE Plus started in January 2000, with two years of funding support. The goal of this project was to continue the development of UNICORE with the aim of producing a Grid infrastructure together with a Web portal. It also included hardening and maturing the system for production, the integration of new functions and more components, and the deployment of further participating sites. The Grid Interoperability Project (GRIP) was a two-year project started in 2001 funded by the European Union to realize the interoperability of Globus and UNICORE and to work toward standards for interoperability in the Global Grid Forum.

The UniGrids project, which started in July 2004 aims to develop a Grid services' infrastructure based on the OGSA. This will transform UNICORE into a system with interfaces that are compliant with the WSRF and that can interoperate with other WSRF-compliant systems. The UNICORE architecture of 2003 is shown in Figure 3; it basically consists of a user tier and a server tier.

User Tier

The UNICORE Client provides a GUI to underlying services. The client communicates with the server by sending and receiving abstract job objects (AJOs) and file data via the UNICORE Protocol Layer (UPL), which uses the Secure Sockets Layer (SSL) protocol. The AJO contains platform- and site-independent descriptions of computational and data-related tasks, resource information, and workflow specifications, along with user and security information. AJOs are sent to the UNICORE Gateway in the form of serialized and signed Java objects, followed by an optional stream of bytes if file data is to be transferred.

Server Tier

The server tier contains the Gateway and the network job supervisor (NJS). The Gateway controls the access to a UNICORE Site (Usite) and acts as the secure entry point accepting and authenticating UPL requests. A Usite

Figure 3: The UNICORE Architecture circa 2003 (Courtesy of Fujitsu Laboratories of Europe) (FZJ = <http://www.fz-juelich.de/>; IDB = incarnation database; NJS = network jobs supervisor; SV1 = Fujitsu System; TSI = targets system interface; UDDB = UNICORE user database)

identifies the participating organization to the Grid with a symbolic name that resolves into the URL of the Gateway. The Gateway forwards incoming requests to the underlying NJS of a virtual site (Vsite) for further processing. The NJS represents resources with a uniform mapping scheme. Each Gateway also contains a target system interface (TSI) that implements the interface to the underlying computational resources. NJS is a stateless daemon running on the target system and interfacing with the local resource manager realized either by a batch system such as Condor or PBS or a Grid resource manager like the Globus Resource Allocation Manager (GRAM).

gLite

EGEE is a project funded by the European Sixth Framework Programme. It is building on emerging Grid technologies and earlier projects, such as the European Union (EU) DataGrid. The project joins together more than 70 institutions in 27 European countries and aims to construct a multi-science Grid infrastructure for Europe. In particular, the project will:

- Provide a secure, reliable, and robust Grid infrastructure.
- Reengineer to a so called lightweight middleware solution, gLite, specifically intended to be used by many different scientific disciplines.
- Attempt to attract, engage, and support users from science and industry, and provide them with technical support and training.

The EGEE project was started by using the existing LHC (Large Hadron Collider) Computing Grid project as its springboard. LCG aimed to provide computing resources

for the analysis of data coming from the LHC at CERN, Geneva.

EGEE began work using the LCG-2 middleware, provided by the LCG project, which was based on the middleware from the EU DataGrid project. In parallel, it has produced the gLite middleware, reengineered using components from a number of sources to produce middleware that provides a full range of basic Grid services. In February 2006, gLite was at version 1.5, and consisted of some 220 packages arranged in thirty-four logical deployment modules. The core gLite components are shown in Figure 4.

Site services include a computing element (CE), which is a gateway to local computing resources, where there is a local resource management system (LRMS). Also, there are worker nodes (WN) and storage elements that are gateways to local storage, which can be disk- or tape-based. Finally, the site service includes a user interface (UI) that gives a user an access point to the Grid.

There are a number of Grid/VO-wide services, these include:

- Security services, including the Virtual Organization Membership Service (VOMS) and the MyProxy Server.
- An information system, called R-GMA, which is a relational version of the Grid Monitoring Architecture system. R-GMA provides a distributed database that aggregates service information from multiple Grid sites. It is used by workload management system (WMS) to collect information on sites and their resources.
- A job management system, which includes a WMS as well as a logging and bookkeeping service. WMS is used to find the best location for a job; it matches

Figure 4: gLite Components

requirements with the available resources. WMS finds CEs from the R-GMA, and schedules jobs using a lazy scheduling algorithm. Logging and bookkeeping services help keep track of a job's status and resource use.

- The data management system includes various catalogues (file, replicas, and metadata) and a file transfer and placement service. This system provides services and protocols to interact with storage elements.

WSRF::Lite

WSRF::Lite is a Perl implementation of the WSRF specification developed at the University of Manchester. Like its predecessor, OGSi::Lite, it uses SOAP::Lite as its Web services tool kit. The architecture of WSRF::Lite is shown in Figure 5. Development of WSRF::Lite is being supported by the Managed Programme of the Open Middleware Infrastructure Institute (OMII) through the

WSRF::Lite WS-Resources can be hosted using the WSRF::Lite container or the Apache Tomcat Server. The state of the WS-Resource can be stored in system memory, in a file or a database.

Figure 5: The WSRF::Lite Architecture

project Robust Application Hosting under WSRF::Lite (RAHWL). WSRF::Lite is released as open source under a dual license scheme (the Perl Artistic License and the OMII modified Berkeley Software Distribution (BSD) license).

WSRF::Lite provides support for the following Web Services specifications:

- WS-Addressing
- WS-ResourceProperties
- WS-ResourceLifetimes
- WS-BaseFaults
- WS-ServiceGroups
- WS-Security

Apache WSRF

In November 2004, Hewlett-Packard (HP) contributed with Java implementations of early drafts of WSRF, WS-Notification (WSN), and WS-DistributedManagement (WSDM) to the Apache Software Foundation. At the same time, the Globus Alliance contributed the WSRF and WSN implementations that it had developed as the foundation for the next generation of the Globus Toolkit for building Grid middleware and applications. For WSRF and WSN, HP and Globus agreed to combine their implementations. To host the donated code and the ongoing development efforts, three new subprojects—Apollo, Hermes, and Muse—were formed within the Apache incubator, a staging area for new projects. The Apache Platform is shown in Figure 6:

- Apollo implements the WSRF specifications.
- Hermes extends Apollo to implement the WSN specifications.
- Muse extends both Apollo and Hermes to implement the WSDM MUWS (management using Web Services) specification.

Due to trademark concerns, Apollo was renamed WSRF, and Hermes Pubscribe. On June 3, 2005, all Apache WSRF, Pubscribe, and Muse projects officially left incubation.

Apache WSRF had a number of design goals:

1. No assumptions are made about the nature of the entity, or entities, being exposed as a WS-Resource. For example, a WS-Resource could be anything from a Java Bean, to a scheduler that is accessed via some proprietary application programming interface (API). The Apache platform provides the hooks for connecting the WS-Resource's operations and properties to the actual entity being exposed as a WS-Resource.
2. Writing and deploying WSRF services should be relatively effortless. For this purpose, the Apache platform provides implementations of all specification-defined operations and a code generator that, given a WSDL document, generates all of the Java classes and configuration files necessary to expose (via the platform) all services found in the WSDL.
3. Services built with Apache WSRF are deployable on any Java-based SOAP platform. Although Apache Axis is bundled with the WSRF distribution, it is not a requirement.

Apache WSRF consists of three parts:

1. A resource invocation framework
2. APIs for the specifications that WSRF consists of (see the section on WSRF Specifications)
3. Implementations of the operations defined by the WS-ResourceProperties and WS-ResourceLifetime specifications.

Note: The APIs and operation implementations of the WS-ServiceGroup specification are not currently provided.

WSRF.NET

WSRF.NET (WSRF.NET; Humphrey et al. 2004) is a toolkit that is implemented on top of the Microsoft .NET framework for developing and deploying WSRF-compliant Web services. WSRF.NET's development was motivated by the need to provide a familiar .NET abstraction for the Grid, to seamlessly interact with the Linux/UNIX platforms supported by the Globus Toolkit, and finally an implementation of WSRF on the .NET platform in order to undertake a full study of its capabilities. In WSRF.NET, the authors of a service annotate their Web Services code with metadata via .NET attributes. WSRF.NET tools process this information to convert the original Web service into a WSRF-compliant service. The WSRF.NET System Architecture is shown in Figure 7.

WSRF.NET services are actually ASP.NET-based Web services, which are the “normal” Web Services exposed via Internet Information Services (IIS) on a Microsoft Windows system.

Figure 6: The Apache Platform (JMX 1.2 = Java Management Extensions (JMX); J2SE 5.0 = Java Platform, Standard Edition (Java SE) version 5)

Figure 7: WSRF.NET System Architecture

The WSRF.NET tools generate a “wrapper” Web service from that written by the author of a service. This service is then executed as part of an ASP.NET worker process, which hosts the service. The IIS dispatches HTTP requests to the service, which internally invokes either a method on a port type provided by the service’s author or a port type defined by WSRF. Before the method is invoked, the wrapper service uses the value of the EndpointReference in the header of the invocation SOAP message to interact with a particular WS-Resource and retrieve state values. These values are then made available to the invoked method and on completion; any changes to these values are saved. Finally, the method result will be serialized and returned to the client by ASP.NET/IIS. A number of WSRF.NET services have been developed and deployed at the University of Virginia; these include job execution, a file system, node information, and a scheduler.

CROWN

The China Research and Development Environment Over a Wide-Area Network is a Web services-based toolkit that allows the deployment of services on remote resources where there are CROWN services. CROWN 2.0 is developed by a research group at Beijing University and was released in September 2005. CROWN is a

service-oriented Grid middleware suite and a testbed for China e-Science users. The CROWN architecture is shown in Figure 8. CROWN consists of the following components:

- Node Server is an extension of a Globus Toolkit 3.9.5 service container, which provides host/remote service deployment as well as dynamic resource information collection and reporting.
- Service Remote Deployment is used for remote service management, quick deployment, and load-balancing purposes.
- Resource Locating and Describing Service (RLDS) is a distributed Grid information service architecture. It is used for collecting of information about resources (hosts) and services.
- S-Club is an overlay based RLDS management mechanism. It uses shortcuts to link all the RLDS services into an overlay network. Each club serves for a certain type of service, while each Grid Information System (GIS) may join one or more clubs.
- CROWN Designer is an Eclipse Plug-in for service development. It supports WSRF/WS-I Service development and deployment. Note that Java Development Tools (JDT) and the Plug-in Development Environment (PDE) are part of the Eclipse development environment.

Figure 8: The Crown Architecture (Courtesy of the CROWN Project) (WfS = Work Flow System)

- CROWN Workflow is a BPEL4WS-based (WSBPEL) modeling tool and execution engine, which includes a graphical tool that supports process monitoring and control.
- CROWN Portal is a Java Server Pages (JSP)-based Web Interface, which provides application integration and user job submission.

OMII

The Open Middleware Infrastructure Institute (OMII) was established in January 2004, initially for three years with £6.5 million budget. Its purpose is to take on

existing e-science Grid middleware and produce high-quality, reusable software. The OMII software architecture, shown in Figure 9, currently consists of client and server software, plus a number of integrated services and sample applications.

The OMII_2 Server Stack

The OMII_2 Server Stack consists of a Web services container based on Apache Tomcat and Axis, with specialized extensions to this container that provide secure message handling between clients and services. The services that are integrated with the server include:

Figure 9: The OMII Architecture (WS = Web Services)

- **Accounts:** Which provides account creation and management, and sets up the access permissions for each individual client.
- **Resource Allocation:** This allows clients to request and be allocated computational and data resources.
- **Job:** This allows a client to submit a job to the server and manages the job requirements.
- **Data:** The Data Service allows remote users to upload and download data files to the service provider.

The OMII Grid middleware also includes software from the managed program:

- **GridSAM** is an open-source Web Service for submitting and monitoring jobs managed by a variety of distributed resource managers (DRMs). The core function of GridSAM is to translate the submission instructions specified in a Job Submission Description Language (JSDL) document to a set of resource specific actions to stage, launch, and monitor a job.
- **Grimoires** is a registry that hosts the description of services and workflows, which a scientist can use to form complex scientific experiments. The Grimoires registry is an implementation and extension of the business logic of UDDI, the de facto standard for publishing and discovering Web Services. The extensions include:
 - The registration of executable activities, such as workflows, are included in the registry along with service registrations,
 - Third-party attachment of executable activities' metadata is supported, which allows publishers and third-party users to publish information about services, such as semantic descriptions, functionality, and service reliability.

OMII_2 Client Overview

The OMII_2 Client includes interfaces to OMII_2 integrated services—the means to set up accounts with service providers; and the ability to request resources from remote service providers and accept offered services, specify and submit jobs, and upload data to the remote service provider—as well as interfaces to OMII sample applications.

PyGridWare

PyGridWare is an implementation of the WSRF and Web Service Notification (WSN) family of specifications. It is compatible with the Java WS Core of GT4. PyGridWare provides APIs and tools for building WS-Resources, its Python bindings can be generated from WSDL, and it incorporates transport layer and message-based security. The architecture of PyGridWare is shown in Figure 10. PyGridWare is based on standard Python software, ZSI (Salz 2007) for SOAP handling, 4Suite and PyXML for XML, and Twisted for the hosting environment and event handling.

PyGridWare provides a relatively lightweight stand-alone container that allows automatic service start-up on the container's start-up—this is in comparison with the Apache Tomcat container, which can be considered relatively heavyweight. There is a basic API for resource persistence and the recovery notification infrastructure. There is a subscription manager/notification producer, as well as a lightweight notification consumer. PyGridWare has a security infrastructure that provides pluggable handlers for WS-Security and secure conversation services. PyGridWare also has support for wrapping legacy codes and command line applications as Grid Services.

Figure 10: The PyGridWare Architecture

Summary of Grid Instantiation Services and Features

Table 1 summarizes the key features and components of all the system instantiations outlined in this section. It should be noted that, apart from gLite and OMII, all the systems follow OGSA and WSRF. Even though this is the case, there is currently no guarantee that these systems may be interoperable, as the underlying WS specifications have not yet been standardized and are still under development.

SUMMARY

This chapter first defined what can be considered a Grid system; namely, enabling-coordinated resource sharing and problem solving in dynamic, multi-institutional virtual organizations. The chapter then briefly gave a recap of the evolution of the Grid, from its origins in the mid-1990s until today. Here the forerunners of the current Grid instantiations were outlined. This was followed by a description of how the various communities working in the field of distributed systems, both commercial and academic, started to converge on a service-oriented architecture with the emergence of Web services-based technologies.

The chapter then detailed the appearance of the Open Grid Services Architecture (OGSA), and the initial instantiation of this architecture, known as the Open Grid Service Infrastructure (OGSI), and noted how this failed for a number of technical and political reasons. This was then followed by a discussion of the Web Services Resource Framework (WSRF), and the various emerging Web Services specifications then followed. The key services offered by a WSRF instantiation were then briefly discussed, including security, informational, data management, scheduling, and administrative services. The chapter then outlined the architecture of various current instantiations of Grid middleware, primarily those based on WSRF, but also some just based on Web services. This section included a table that summarized the key features of the aforementioned Grid instantiations.

CONCLUSION

The Grid concepts and infrastructure has evolved from its early days of fulfilling the requirements of integrating high-performance computing centers in the United States through to today's vision of providing an Internet-wide virtual environment in which dynamic services represent underlying resources, which can be used by a wide range of applications.

The Grid provides a dynamic wide area environment that supports distributed applications. This is not new, as there have been a number of previous systems that have attempted to provide similar environments, the most notable ones being the OSF's Distributed Computing Environment (DCE) and CORBA from the Object Management Group (OMG). Both of these systems are still being used, but neither has been widely taken up and adopted by academia, industry, and business. The

reasons for this are outside the scope of this chapter, but can be assumed to be both technical and political. The important fact is that experiences from using these and other Internet-based distributed environments have fed into the Grid architecture and the instantiations that use WSRF. For example, the competing specifications for Web services-based events—WS-Eventing (Box et al. 2004) and WS-Notification (Graham and Murray; Chappell and Liu) both have features from earlier systems, such as CORBA's notification service (CORBA Notification).

Not only has the convergence of the architecture and standards used driven the emergence of the Grid concepts, in addition the speed and cost of the underlying hardware infrastructure has enabled its realization between resources that are not just hosted by high-performance computing centers, but also between smaller entities and business. This latter aspect has effectively lowered the barrier for entry into the Grid community, which has meant that not only has a wider user base become able to use these technologies, but also the number and type of resources that have become part of the hardware fabric has become increasingly diverse, ranging from traditional ones to sensor networks and other mobile devices.

Even though some may try to sell the Grid as a panacea for all applications, it is becoming clear that a variety of loosely coupled distributed applications are the most suitable for today's systems. These applications include:

- Parameter Sweeps (Condor; Nimrod; NetSolve) are applications that consist of large sets of independent tasks and arise in many fields of science and engineering. Due to their flexible task synchronization requirements, these applications are suited to large-scale distributed platforms, such as the Grid.
- Relational databases are important components associated with many distributed applications. Middleware offerings, such as OGSA-DAI, that can be used to assist with access and integration of data from separate sources via the Grid are increasingly important. Equally, software such as OGSA-DQP that should enable effective and efficient query processing across these distributed databases is being adopted too.
- Another area that has received attention is coupled simulations; these are large-scale applications that are executed on distinct resources, such as a cluster, and the output of one application becomes the input of another. Research areas, such as meteorology and oceanography (Joint Centre for Hydro-Meteorological Research) are developing these types of Grid application.
- Sharing potentially expensive resources is another popular area in which Grid technologies are being applied. The resources may be computational ones, or those used for data storage. Alternatively, the resource may be something akin to the equipment hosted by the Network for Earthquake Engineering Simulation (NEESGrid) project (large shake tables, centrifuges, and tsunami wave tanks), which is a U.S. national collaboratory for earthquake engineers.

- A Grid workflow is an automation of a process in which documents, information, or data pass from one service to another for processing, according to a set of procedural rules. A workflow can be composed of other workflow elements and used for building higher-level composite services. There are now many Grid-based workflow systems being used in business and academia (Yu, J., and R. Buyya 2005).
- Distributed data analysis is another area, similar in concept to parameter sweeps, but one in which the data are distributed and analyzed at remote end points. The classic example of this is the Grid infrastructure being set up for the Large Hadron Collider (LHC) Computing Project (LCG) at CERN.

It is clear that the drive for reliable middleware for wide-area distributed computing is now being met by instantiations of WSRF, based on standard Web Services technologies along with a suite of specifications that standardize a number of underlying core services and their attributes. Grid middleware based on a service-oriented architecture is now being increasingly taken up in science, engineering, business, and industry, and being used to provide an infrastructure to support a wide-range of diverse distributed applications.

GLOSSARY

- CROWN (China Research and Development environment Over Wide-Area Network) Grid:** Middleware being produced by a number of institutions in China.
- EGEE:** Enabling Grids for E-science.
- gLite:** Middleware being produced by the EGEE project.
- GSi:** Grid Security Infrastructure.
- JSDL:** Job Submission Description Language.
- MDS (Monitoring & Discovery System):** A component provided in the Globus Toolkit that provides information about the available resources and their status.
- OASIS:** Organization for the Advancement of Structured Information Standards.
- OGF (Open Grid Forum; formerly known as the Global Grid Forum [GGF]):** A body that is attempting to standardize and document the processes and protocols that are, or will be, required to construct Grids.
- OGSA (Open Grid Services Architecture):** describes an abstract architecture for a service-oriented grid environment.
- OGSA-DAI (Open Grid Services Architecture—Data Access and Integration):** Grid services that allows data access to resources such as databases and files using Web Services.
- OMII:** Open Middleware Infrastructure Institute.
- SOA:** Service-oriented architecture.
- SOAP:** Simple object access protocol. Provides a standard, extensible, composable framework for packaging and exchanging XML messages between a service provider and a service requester.
- UDDI (Universal Description, Discovery, and Integration):** A platform-independent XML-based registry for publishing information about service provider and their services.

UNICORE (Uniform Interface to Computing Resources): A Grid middleware.

Virtual Organization (VO): Consists a set of individuals and/or institutions having direct access to computers, software, data, and other resources for collaborative problem solving or other purposes.

WSDL (Web Services Description Language): An XML-based language for describing Web Services.

Web Services Resource Framework (WSRF): A set specifications dealing with the association of Web Services with stateful resources.

INTRODUCTION

This chapter addresses Grid computing implementation that was introduced in Chapter 139. Grid computing allows people to use geographically distributed, networked computers and resources collectively to achieve high-performance computing and resource sharing. The implementation of grids has been evolving since the mid-1990s. Early Grid computing work in the early to mid-1990s focused on customized solutions—that is, projects developed in-house software to achieve the interconnections and Grid computing faculties. The early experiences provided the impetus for later standardized work. One of the most important technical aspects of Grid computing is the use of standard Internet protocols and open standards. The use of standardized technologies is critical to the wide adoption of Grid computing. It has now been recognized that XML and Web services provide a very flexible standard way of implementing Grid computing components. We will begin by briefly outlining Web services, XML, and Web Services Description Language (WSDL). With that basis, we can then describe the components of a Grid computing infrastructure.

GRID COMPUTING INFRASTRUCTURE

Web Services

Web services are software components designed to provide specific operations (“services”) that are accessible using standard Internet technology. They are usually addressed by a uniform resource locator (URL). A URL is a string of characters that is used to identify a resource on the World Wide Web. URLs conform to a defined syntax and include the protocol used to access the resource. For example www.cs.uncc.edu is the URL of the main computer science page at UNC-C, to be accessed by hypertext transfer protocol (HTTP). Web services are designed to be accessed over a network by other programs. The Web service itself may be located anywhere that can be reached on the Internet. A Web service can be used as a front end to an application to allow the application to be accessed remotely through the Web service.

Web services build on previous distributed computing concepts. An early form of distributed computing was the remote procedure call (RPC) introduced in the 1980s. This model allows a local program to execute a procedure on a remote computer and then get back results from that procedure. Later forms of distributed computing introduced distributed objects, for example CORBA (Common Object Request Broker Architecture) and Java RMI (remote method invocation). A fundamental requirement of all forms of RPCs is the need for the calling programs to know details of accessing the remote procedure. Procedures have input and output parameters with specific meanings and types. The specific calling details need to be known by the calling program. These details can be described using an interface description language (IDL). Web services use an XML-based IDL, which provides a very flexible and elegant solution, as we shall see.

RPCs introduced an important concept, that of a client-server model with a service registry, which is retained for Web services. In a client/server model, the client accesses the server for a particular operation. The server responds accordingly. For this to happen, the client needs to identify the location of the required service and know how to communicate with the service to get it to provide the actions required. You can achieve these two things by using a service registry, which is usually a third party, in a structure now known as a service-oriented architecture (SOA), as shown in Figure 1. The sequence of events then is as follows: First, the server (service provider) “publishes” its service(s) in a service registry. Second, the client (service requestor) can ask the service registry to locate the service. Third, the client (service requestor) binds with the service provider to invoke the service. An interface description language (IDL) can be used to describe the service interface.

Key aspects of using Web services in a client-registry-service model is the use of XML and Internet protocols to make the arrangement completely platform-independent and nonproprietary. Let us first consider XML and then the XML language used to describe the Web service functionality, called WSDL. Then we will discuss the

Figure 1: Service-oriented architecture

packaging communication protocols used to transmit the XML documents, known as SOAP.

XML (Extensible Mark-up Language)

Mark-up languages provide a way of describing information in a document such that the information can be recognized and extracted. The Standard Generalized Mark-Up Language (SGML) is a specification for a mark-up language ratified in 1986. A key aspect of SGML is using pairs of named tags that surround information (the body), a begin tag `<tag_name>` and a matching end tag `</tag_name>`, where `tag_name` is the name of the tag. Tags can be nested.

Hypertext Markup Language (HTML) is a subsequent mark-up language using a similar approach but specifically designed for Web pages. “Hypertext” refers to the text’s ability to link to other documents. “Markup” refers to providing information that tells the browser how to display the page and other things. The meanings of tags in HTML are predefined—for example, `<B>` to start bold text and `</B>` to end bold text. Certain tags in HTML do not necessarily require end tags, such as `<P>` alone, which indicates the start of a new paragraph. Many tags can have attributes that specify something about the information between tag pair. For example, `<FONT FACE=Times COLOR=red>` specifies that the text in the body will be red and in Times font. The concept of attributes is very important and is used extensively in XML.

XML is very important standard mark-up language; it is a “simplified” SGML, ratified in 1998. XML was developed to represent textual information in a structured manner that could be read and interpreted by a computer. XML is a foundation for Web services, and Web services now form the basis of Grid computing. Two key aspects of XML are:

- Names of tags and attributes are not predefined as they are in HTML. Tags can be defined broadly at will but must be defined somewhere and associated with the document that is using the named tags.
- Tags are always used in pairs delineating information to make it easy to process. (There is an exception to this

rule when the body between the tags is empty, in which case the opening and closing tags may be combined into a single tag of the form `<tagName/>`.)

Tag names and meanings can be created to suit the application and become a specific XML language. As such, an infinite number of XML languages could be invented, and many have already been.

Namespace Mechanism

If XML documents are combined, there is the problem of ambiguity if different documents use the same tag names for different purposes. The namespace mechanism provides a way of distinguishing tags with the same name, and is used widely within XML documents. With the namespace mechanism, tag names are given an additional namespace identifier to qualify it. The fully qualified name is given by namespace identifier plus the name used in the document. The namespace identifier used is a uniform resource identifier (URI). A URI is a string of characters used to identify a resource. An extension of URIs to cover international language symbols is called an international resource identifier (IRI). Typically, a namespace uses a URL. (URLs are a subset of URIs and include the protocol used to access the resource.) Even though the namespace may be a URL, the URL is only used as a means of distinguishing tag names and solve any ambiguity. The URL does not need to exist. However, typically one would place a read-me document at the location if a URL is used. This practice has been formalized into providing a Resource Directory Description Language (RDDL) document.

Rather than simply concatenate the namespace identifier with the local name throughout the document, the names in the document are given a prefix separated from the name with a colon. The association of namespace identifier and prefix is done using the `xmlns` attribute in the root element, in which the qualifying name is the attribute’s value. There can be more than one namespace attribute, each associated with a different prefix, and there will also be a default namespace defined for names without a prefix.

Schemas

So far, we have not said which tags are legal in a document and how the tags are associated with a particular meaning and use. One way to define which tags are legal in a particular XML document is to describe them within the document in the document type definitions (DTD). However, this approach has serious limitations in terms of system integration and flexibility and is not currently used for Web services. In fact, they are not allowed in SOAP messages (the messaging protocol used for XML documents; see below). An alternative and much more powerful approach is to define legal tags in another XML document, called a “schema,” and associate that schema document with the content XML document, either explicitly or by common agreement between the parties. XML schemas, also expressed in XML, provide a flexible way of handling legal element names and have the notation of data types. This approach also leads to different XML languages, each with its own schema. Once a schema exists for a particular XML language, it can be associated with XML documents, or *instances* of possible documents using the schema.

Since a schema is also an XML language, there should also be a schema for schemas. The schema for the XML schema is predefined and specified in the XSD (XML schema definition) language. More details on XML schemas can be found at the W3C website (W3C Architecture Domain XML Schema, n.d.).

SOAP

SOAP is a communication protocol for passing XML documents, standardized by the W3C organization (World Wide Web Consortium). Originally, SOAP stood for simple object access protocol. However, the spelled-out version has since been dropped because this name was not accurate; specifically the protocol does not involve object access. The draft W3C specification (Gudgin et al. 2003) describes SOAP as follows:

SOAP Version 1.2 (SOAP) is a lightweight protocol intended for exchanging structured information in a decentralized, distributed environment. It uses XML technologies to define an extensible messaging framework providing a message construct that can be exchanged over a variety of underlying protocols. The framework has been designed to be independent of any particular programming model and other implementation specific semantics.

SOAP provides mechanisms for defining the communication unit (a SOAP message), the data representation, error handling, and other features. SOAP messages are transported using standard Internet protocols, most likely HTTP.

Web Service Definition Language

In the Web services approach, there needs to be a way of generally and formally describing a service, what it does, how it is accessed, etc. in an IDL. The World Wide Web Consortium (W3C) has published an XML standard for

describing Web services called Web Service Description Language (WSDL). WSDL version 1.1 was introduced in 2001. WSDL version 2 was introduced in 2004 and made a number of clarifying changes.

A WSDL document describes three fundamental properties of a service:

- What it is—operations (methods) it provides
- How it is accessed—data format, protocols
- Where it is located—protocol specific network address

The abstract definition of the operations is contained in the element called *interface* (called a *portType* in WSDL version 1.1). This element contains elements called *operation* that specify the types of message sent and received (input and output elements). These operation elements loosely correspond to a method prototype. The messages are further defined in terms of data types being passed in the type element. The *binding* element describes how to access the service—that is, how the elements in abstract interfaces are converted in actual data representations and protocols (e.g. SOAP over HTTP). In WSDL version 2, the *service* element described where to find the service. The *service* element contains the *endpoint* element, which provides the name of the end point and physical address (URL). (The *service* element was defined differently in WSDL version 1.1. The *port* elements describe the location of a service and the *service* element defined a named collection of ports.) More information on WSDL version 2 is given by Booth and Liu (2005).

Putting It Together

The basic parts of a service-oriented architecture are the service provider (server), service requestor (client), and service registry. Web services can use a UDDI (Universal Description, Discovery and Integration) registry, which itself is a Web service. UDDI is a discovery mechanism for Web services and provides a specification for modeling information targeted primarily toward business applications of Web services. For Grid computing applications, other ways of forming service information for discovery are available including using WS-Inspection Language (WSIL) (IBM 2001). After a registry is populated with Web service entries, the client can access the registry to find out whether the desired Web service exists in the registry and if so where it is located. The registry responds with the identification of the server capable of satisfying the needs of the client. Then, the client can access the server for the Web service interface. The server responds with a WSDL document describing the service and how to access it. The client can then send the Web service a request for an operation. The result of the operation is returned in a message from the Web service. All messages in this architecture are SOAP messages. It would be feasible for the registry to return the WSDL interface document and then with this in hand, the client could make a request immediately to the Web service without asking for its WSDL interface document.

Note that the registry itself has to be known both to the client and the service provider. Of course, a registry is

Figure 2: Web services environment

unnecessary if the client knows about the Web service already and the location of the Web service never changes. However, in a dynamic and distributed Grid computing environment, a registry or information service is necessary. Now let us look at how to implement a Web service and client. Web services are generally “hosted” in a Web service container—that is, a software environment that provides the communication mechanisms to and from the Web services. Web services are deployed within such an environment. There are several possible environments that are designed for Web services, notably, Apache Axis (Apache eXtensible Interaction System), IBM Websphere, and Microsoft .NET. The J2EE (Java 2 Enterprise Edition) server container is also a candidate for hosting Web services especially in enterprise (business) applications. Apache Axis requires an application server. It can be installed on top of a servlet engine such as Apache Jakarta Tomcat. However, it could be installed on top of a fully fledged J2EE server.

For the implementation, it is convenient to connect the service code to the client through two Java classes that act as intermediaries, one at the client end called a “client stub” (also called a “client proxy”) and one at the service end called a “server stub” (also called a “skeleton”). These stubs provide a structured way to handle the messaging and different client and server implementations. Interaction is between the client and its stub, between the client stub and the server stub, and between the server and its server stub. The interaction between the stubs is across the network using SOAP messages. The client stub is responsible for taking a request from the client and converting the request into a form suitable for transmission, which is called “marshaling.” The client stub is also responsible for receiving responses on the network and converting to a suitable form for the client. The server stub is responsible for receiving a SOAP request from the client stub and converting it into a suitable form for the service, called “unmarshaling.” The server stub also converts the response from the service into a SOAP message

for the client stub. The resulting Web service environment is shown in Figure 2.

Web services deployment descriptor (WSDD) is an XML language used to specify how to deploy a Web service. More details of Web services and their deployment can be found in Graham et al. (2005).

Grid Computing Standards

Early Grid Computing Standards

Although Web services are very attractive as a basis for creating a grid infrastructure, Grid computing requires some way of representing state—that is, values that persist from one invocation of the service to the next. Pure Web services do not have state. Another feature needed in Grid computing is the ability to make a service transient—that is, to be able to create and destroy a service. Typically, transient services are created by specific clients and do not outlive their clients. Web services are usually thought of as nontransient and do not have the concept of service creation and destruction. Hence, some changes are needed to the Web services approach if it is to be adapted to Grid computing.

The Global Grid Forum (GGF), in developing standards for Grid computing, focused on using Web services and originally developed two interrelated standards called Open Grid Services Architecture (OGSA) and Open Grid Services Infrastructure (OGSI). The term *Grid service* was introduced as the extended Web service that conforms to the OGSI standard. OGSA defines standard mechanisms for creating, naming, and discovering Grid services and deals with architectural issues to make interoperable grid services. OGSA is described in the seminal paper “The Physiology of the Grid: An Open Grid Services Architecture for Distributed Systems Integration” by Foster, Kesselman, Nick, and Tuecke (2002). OGSI specifies the way that clients interact with grid services (that is, service invocation, management of data, security mechanism, etc.). These standards appeared in the early 2000s and

were implemented in the Globus Toolkit version 3 in 2003. In OGSI, the Web service model was extended to enable state to be implemented. An extension of WSDL was invented called Grid Web Service Description Language (GWSDL) to support the extra features in Grid services not present in Web services. However, OGSI had a very short life. The Grid community at large did not embrace OGSI, which was seen by many as too complex. The push was made to align OGSA more closely with Web services so that existing Web service tools could be used. This led to the Web Services Resource Framework, which is discussed below.

Web Services Resource Framework

Web Services Resource Framework (WSRF) presents a way of representing state while still using the basic WSDL for both Web services applications in general and Grid computing in particular. Instead of modifying the WSDL to handle state, the state is embodied in a separate resource. Then, the Web service acts as a front end to that resource as illustrated in Figure 3. The resource still needs to be described in the WSDL file, which is achieved in a resources properties section of the WSDL file. The combination of a Web service and resource in this framework is called a WS-Resource. The resource in this description can mean anything that has state and requires access, such as a database, or variables of a Web service that need to be retained between accesses.

The WSRF specification calls for a set of six Web services specifications:

- WS-ResourceProperties
- WS-ResourceLifetime
- WS-Notification
- WS-RenewableReferences
- WS-ServiceGroup
- WS-BaseFaults

WS-ResourceProperties describes how resources are defined and accessed. Other aspects of WSRF deal with using multiple resources, resource lifetime, and how to obtain notification of changes (WS-Notification).

Web services are traditionally addressed simply by a URL, but this does not provide much functionality. A specification called WS-Addressing has been introduced to provide more than just the URL, and it is particularly

relevant to WSRF, as it provides a way of specifying resources as well as the Web service. WS-Addressing introduced a construct called an end-point reference (EPR). An end point is the destination where the service can be accessed. An end-point reference is a structure that provides the end point address as a URI (more recently as an IRI). The structure also provides other, optional information, consisting of reference parameters and metadata. The metadata include information about the behavior, capabilities, and policies of the end point.

According to the W3C document “Web Service Addressing 1.0 Core” (Gudgin and Hadley 2005), the reference parameters are “namespace qualified element information items that are required to properly interact with the endpoint.” For WSRF, the reference parameter feature is used to convey the identity of the resource. (WS-Addressing originally included a parameter named “reference properties” that was used.) The end-point reference is then called “WS-Resource-qualified” (Czajkowski et al. 2004). The resource identity can simply be an assigned number or a character string. It is called a “key” by Ananthakrishnan et al. (2005). The end-point reference typically would be returned when the WS-Resource is created and can be used to identify it for access and destruction.

Software Components for Grid Computing

The Globus project (Foster 2005; The Globus Toolkit 2006) provides reference implementations for Grid computing standards and is a de facto standard itself. The approach taken by Globus is to provide a toolkit of component parts, which can be used separately or, more likely, collectively for creating a grid infrastructure. The Globus Toolkit has gone through four versions from the late 1990s to 2005. Many of the ideas embodied in Globus were present from version 1 of Globus, including job submission and security mechanisms. Globus version 2 describes the basic structural components within a grid security environment as three pillars:

- Resource Management
- Data Management
- Information Services

This division of parts essentially remains in the current release. The principal task of the resource management

Figure 3: Web Services Resource Framework

component, GRAM (Grid Resource Allocation Manager), is to submit jobs. These jobs are submitted to local resources via a local scheduler. GRAM provides an interface to local schedulers such as load sharing facility (LSF) (Platform 2006), Portable Batch System (PBS) (Altair Grid Technologies 2006), Sun Grid Engine (SGE) (Sun N1 Grid Engine 6 2006), and Condor (Thain, Tannenbaum, and Livny 2003), which then pass the job onto the computer resources. Jobs often need data files, and the data management component provides the ability to transfer files to the required places. The key component is the grid version of FTP called GridFTP. Grid Information Services (GIS), as the name suggests, provide information about the grid infrastructure. The information directory service in Globus version 2 is called Metacomputing Directory Service (MDS), which enables Lightweight Directory Access Protocol (LDAP)-based information structures to be constructed. Globus version 2 Grid Resource Information Service (GRIS) provided information on the computational resources (configuration, capabilities, status). The Grid Index Information Service (GIIS) was also provided for pulling together information.

Globus version 3 retains the basic components of version 2 but is implemented using OGSA/OGSI standards. Globus version 4, introduced in 2005, builds on previous versions and implements the components using the WSRF standard. Note, however, that versions are not backward-compatible, as the standards they followed are not compatible; although some pre-Web-services components remain in later Web-service versions. Also note that even in the WSRF Globus version 4, for efficiency reasons, that some functionalities are not Web services. For example, GridFTP is not a Web service, although there is a Web-service front-end available (reliable file transfer [RFT] service, see below). A common feature of all versions (1, 2, 3, and 4) is the use of the public key infrastructure (PKI) for security. Security is considered in detail in the following section.

GRID SECURITY

Basic Security Concepts

It is clearly necessary in the distributed structure of a Grid infrastructure to secure communication and secure access to resources to stop unauthorized access and tampering. Security is also required in important transactions on the Internet, and hence similar mechanisms that are used there can be used in Grid computing, following the strategy that standard Internet protocols should be used for widespread adoption of Grid computing. There are some special additional security requirements for Grid computing. First, secure communication is needed not only between users but also between users and resources, such as computers, and between the resources themselves. Second, specifically related to communication between resources themselves, it is necessary to delegate the user's authority to programs to act on the user's behalf, including at remote sites, while preferably requiring the user to sign on only once (single sign-on). Before developing the full solution to these factors, let us first consider general security concepts.

Two critically important security concepts are:

- *Authentication*—The process of deciding whether a particular identity is who he, she, or it says he, she, or it is (applies to humans and systems)
- *Authorization*—The process of deciding whether a particular identity can access a particular resource, including whether the specific type of access is allowed. This latter aspect is commonly called Access control.

The traditional way to authenticate users is for each to have a username and password. Users who wish to be authenticated enter their username and password, which are sent to a server through the network. Upon receipt, the server validates the username and password and responds accordingly. There are two aspects to make such password-based authentication workable:

- Information needs to be sent in a form that is unintelligible except to the parties involved, otherwise the username and password could be stolen.
- The identity of the sender has to be proved in some fashion.

The term *data confidentiality* is used to describe the protection of the information exchange from eavesdroppers, and this is done by scrambling the binary patterns in a process called “encryption.” There are many algorithms that could be used to encrypt data. Usually, the algorithm is not kept secret. Instead a number used in the algorithm is kept secret. This number is called a “key.” To make it difficult to discover the key, the key chosen is a very large number, typically 128 bits or more. In secret key cryptography or symmetric key cryptography, the same key is used to encrypt the data as to decrypt it. In that case, both the sender and the receiver need to know the key, but the key has to be kept secret from everyone else.

It is possible to devise an algorithm that uses two keys, one to encrypt the data and one to decrypt it. This is known as “asymmetric key cryptography.” In this form of cryptography, one key, called the “public key,” is made known to everyone, while the other key, called the “private key,” is known only to the owner. Data encrypted with the receiver's public key can be decrypted only by the receiver using his or her private key. Asymmetric key cryptography is also called “public key cryptography” because of the use of one key being made publicly available. In asymmetric cryptography, there is no known practical way of discovering one key from the other key. However, it is slower to encrypt/decrypt data using public key cryptography than using secret key cryptography. In addition, if you were to encrypt data using a receiver's public key, the receiver cannot be sure of the identity of the sender, as everyone has access to the public key. So mechanisms need to be in place to confirm identities.

Data integrity is the name given to ensuring that data were not modified in transit (either intentionally or by accident). Data confidentiality—that is, protecting the data from eavesdroppers—is obtained by encrypting the data. To achieve data integrity, a binary pattern called a “digest” is attached to the data, computed from the data using a hash function. The digest is different

Figure 4: Checking digital signatures

if the data have been altered in transit. To achieve both data integrity and authentication, the digest is encrypted with the sender's private key to create a digital signature, which is attached to the data instead of the digest itself. The receiver can check the digital signature by decrypting the signature (with the sender's public key) and comparing the result with the digest created separately from the received data, as illustrated in Figure 4. Note that if data can be decrypted with the sender's public key, it can only have been encrypted with the sender's private key and hence by the sender.

However, digital signatures alone are not sufficient to ensure that the data are truly from the sender. It is possible that the public key is a fake—i.e. from an attacker instead of from the trusted sender. To cover this possibility, users are issued certificates, which are digital documents listing the user's specific public key. A trusted third party called a "certificate authority" (CA) certifies that the public key does in fact belong to the user named on the certificate.

Certificates are comparable to driver's licenses and passports as a form of identity. The most widely used certificate format is the X.509. Version 1 of this format was defined in 1988 by International Telecommunications Union (ITU). Versions 2 and 3 added some fields. Information provided in the certificate includes the name and digital signature of the issuer (certificate authority), algorithm used for signature, name of the subject (user), subject's public key, public key algorithm used, and validity period. Names have to be unique and recognizable. To this end, the X.500 distinguished name format is used. The X.500 naming format is a hierarchical list of attributes that is intended to make the name globally unique. An example of a distinguished name is: /C=us/O=University of North Carolina at Charlotte/OU=Computer Science/CN=Barry Wilkinson, where C indicates country, O the organization, OU the organizational unit, and CN the common name. Another possible attribute is /L for location. How names are constructed must be agreed on by all parties and is part of written certificate policies. There are obviously many possibilities, even within the constraints of the X.500 distinguished name format, from highly hierarchical to almost flat.

To obtain a signed certificate for themselves, users first contact a certificate authority. Generally, the user generates his or her own public/private key pair and sends the public key to the certificate authority, keeping the private key in a very secure place. The certificate authority returns a signed certificate. The certificate authority has to be given some means of proving the identity of the user, which may require some off-line procedure in which humans communicate—i.e. the user communicates with the manager of the certificate authority. Once the user has a signed certificate, the certificate can be sent with the data to other parties. Alternatively, the data can be sent without the sender's certificate and the receiver retrieves the sender's certificate from a public place. Either way, the receiver of a user certificate can verify the certificate by verifying the CA's signature. Then, it can trust the sender's public key contained in the certificate. It is necessary for the receiver to have the certificate authority's public key, which is obtained from the certificate authority's own certificate. (The certificate authority signs its own certificate.) This process works if one can trust the certificate authority and its public key.

There are several protocols that use the above PKI, the most notable being SSL (secure sockets layer), which can be added on top of protocols such as HTTP and FTP. The SSL protocol involves exchanging a sequence of messages that includes randomly generated numbers, and provides for mutual authentication, although in many Web applications the user is not authenticated, only the server. Commercial certificate authorities exist, such as VeriSign and Entrust Technologies. Web browsers have built-in recognition for such trusted certificate authorities to allow SSL and other secure connections.

Certificates have a valid time period specified on the certificate defined by "not before" and "not after" parameters. Typically, the validity period set is quite long, say one year or five years. It is critically important to maintain the private key very securely, usually on your local computer encrypted using a password. The private key will be used to encrypt data that are to be decrypted with your public key and to decrypt data that was encrypted with your public key.

At the beginning of this section, we differentiated between authentication (the process of deciding whether a particular identity is who he says he is), and authorization (the process of deciding whether a particular identity can access a particular resource). A simple authorization mechanism is the access control list found in UNIX/Linux based systems and also in Windows systems. An access control list is a table listing the users and groups of users allowed to access particular resources and what type of access is allowed. In a UNIX/Linux-based system, for example, access to files and directories are controlled by an access control list. The access control list concept can be carried over to Grid computing systems, although the distributed nature and different administrative domains of resources of a grid make it desirable to have further mechanisms, which we shall discuss in the next section.

Grid Security Infrastructure

Grid Security Infrastructure (GSI) is the Grid computing security that is implemented in Globus; it is a GGF standard. GSI uses PKI and the SSL protocol for mutual authentication. More recently, WS-Security can be used, which is an extension to SOAP messaging for security. Grid computing projects usually form their own certificate authorities. The Globus Toolkit provides an implementation of a certificate authority called “simpleCA” that can be used for small projects. We shall discuss CAs for larger projects later. First let us consider additional security features required for Grid computing.

Delegation

Delegation is the process of giving authority to another identity (usually a computer or process) to act on one’s behalf. Implicit in delegation is the concept of single sign-on, which enables users and its agents to acquire additional resources without repeated authentication. Usually, the user’s private key is password-protected (encrypted with a password) and each time a user has to access the private key to perform a security-related operation, the user would need to type in the password. Single sign-on avoids this practice. Delegation is achieved by the use of additional certificates called “proxy certificates” (loosely called “proxies”). Proxy certificates are signed by the user (or the proxy entities themselves in a chain of trust) rather than by the certificate authority. Proxy certificates are created with new public and private keys and the user’s name with the attribute /CN=proxy added to the name. The private key of the proxy is not password-protected, only file-system-protected in the user’s file system. (If it were password-protected, it would defeat the purpose of reducing the need for typing passwords). To combat this insecurity, the validity period of proxy certificates is set to be short, say 12 hours, and, of course, not past the validity of the original user certificate from which it is based.

Suppose the user wants to delegate his authority to a third party to act on his behalf. This third party requires a proxy certificate signed by the user and she makes a request to the user for a signed proxy certificate, just as the user asked a certificate authority for a certificate for himself. Acting as his own proxy certificate authority, the user returns a proxy certificate signed by himself. The user also sends her own certificate. The third party

requires the user’s certificate to be able to validate to the proxy certificate, just as the CA’s certificate is required to validate the certificate. As described by Ferreira et al. (2004), both the certificate and the proxy certificate are checked for the user’s name (the proxy with the added proxy attribute). Once all validation is done, the third party can issue requests to others on the user’s behalf, using the proxy’s private key to encrypt messages.

The delegation process can also be chained—that is, the third party having the proxy can generate a proxy to another party using the same procedure as described for the user giving its proxy. In that case, the proxy issuing its proxy certificate signs it. Proxy certificates are part of the Globus GSI and are proposed as a standard (GT 4.0 Security: Key Concepts, n.d.). Proxies are used for delegation locally as well as remotely. Creating a proxy is one of the first actions a user must do when using Globus with the command `grid-proxy-init`.

Credential Management

A certificate and corresponding private key are collectively called the “credentials” (i.e. user credentials, proxy credentials, host credentials, etc.). However, the private key is available only to the owner, and the word *credentials* is used quite loosely as not including the private key, which should not be transferred under any circumstances. It is convenient to have a central credential repository to store proxy credentials, which then can be accessed as required rather than having to maintain the credentials in several places. Globus version 4 provides a proxy credential repository called MyProxy (MyProxy Credential Management Service 2006). MyProxy is accessed by other components to store, retrieve, and renew proxy credentials. These components include grid portals and job managers, as described later.

Authorization

To connect to a remote site, you need permission (authorization) and an account. The simplest authorization mechanism is a form of access control list called a “grid-map file.” The grid-map file is a file maintained at the site and holds list of user’s distinguished name (as given on their certificates) and their corresponding local account name. An entry might be: “C=us/O=University of North Carolina at Charlotte/OU=Computer Science/CN=Barry Wilkinson” abw where abw is the local username. The user’s local access rights apply. It is allowable to map more than one user to a single local account if desired—i.e., to have a group working with a single account.

The grid-map file approach, although straightforward and implemented in GT 4.0, does not scale well. It requires each resource in the grid to maintain a separate grid-map file containing entries for all those expected to use the site. For a system with more than two or three sites, this becomes unmanageable.

Large-Scale Grid Computing Security Infrastructure

There are many issues in creating a large-scale Grid computing infrastructure. In the previous section, we saw

that the traditional access control list, although feasible for a small system, is unworkable for a large system. Grid computing is all about large-scale geographically distributed infrastructures. Many of the problems for large-scale structures are still open research problems with many potential solutions being suggested. Building a large-scale grid system around the basic tools of GSI will require additional scalable tools.

Authentication

Rather than have a single certificate authority, one might choose to use multiple certificate authorities, perhaps one at each major site in the Grid. This was done for an undergraduate Grid computing course taught across North Carolina (Wilkinson and Ferner 2005). Each user receives a certificate issued by one of the certificate authorities. When the certificate is submitted to another site for authentication, it is necessary for that site to trust the issuing certificate authority as illustrated in Figure 5. Globus provides for the configuration of trusting multiple certificate authorities. The certificate of the certificate authority and a configuration file defining the distinguished names of the certificates signed by the certificate authority are simply loaded in the trusted certificate directory of Globus. Each Globus installation would need these two files for each certificate authority to be trusted. It is clear that this approach is not scalable or flexible for a grid that might grow or change in configuration. However, maintaining a list of trusted certificate authorities is the way a Web browser handles trusted certificate authorities.

PKI trust can be chained. Suppose A receives B's certificate for validation, and B's certificate is signed by a certificate authority C, whom A does not immediately trust. If A is also given C's certificate, which is signed by certificate authority D, whom A does trust, then A can obtain the public key of B's certificate authority and trust it. One could construct a hierarchical, tree-like certificate authority structure, with a single root certificate authority that everyone trusts. This root certificate authority signs certificates of certificate authorities below it, which themselves can sign certificates of certificate authorities

below and so on until a certificate authority is reached that signs users' certificates. If A wishes to accept B's certificate, it needs to work back from B's certificate to the root certificate authority that it trusts. A certification path is established that has to be navigated. A single-root certificate authority has the disadvantage that if the root is compromised, the whole system is compromised. However, the tree structure may be convenient in some organizations having a similar physical hierarchical structure.

There are other certificate authority configurations using the feature that certificate authorities can be cross-certified. Here, a pair of certificate authorities sign each other's certificates. Usually, a user trusts the certificate authority that signs its own certificate. If a group of certificate authorities are cross-certified in pairs and there is a path between the certificate authority of A and the certificate authority of B, one can establish trust between A and B. This avoids the single trust point of a tree structure and also enables arbitrary PKIs to be formed.

If more than one PKI already exists, either a tree or some arbitrary network, a *bridge certificate authority* may be attractive, which forms a trust between one certificate authority in one PKI and one certificate authority in another PKI. Each such certificate authority is cross-certified with the bridge. The advantages of a bridge configuration is that it reduces the number of cross certificates from $O(N^2)$ to $O(N)$, where N is the number of CAs in the configuration, and the whole configuration is not compromised if a single CA is compromised. An example of a grid using bridge cross-certification is the SURAGrid (SURA NMI Testbed Grid PKI Bridge Certification Authority, n.d.).

Authorization

Scalable authorization structures are also needed in larger grids. The Communication Authorization Service (CAS) is a component, available in Globus versions 3 and 4, designed to handle the authorization of many distributed users and many resources. CAS maintains information on what rights the grid community grants to users.

Figure 5: Certificate authorities with mutual trust

The user first asks CAS for permission to use a resource. CAS gives the user proxy credentials with specific rights—that is, a policy statement signed by CAS. The user then presents these credentials to the resource. The resource trusts credentials signed by CAS and accepts the request if the policy statement contained in the credentials authorizes the user for the specific request.

VOMS (Virtual Organization Membership Service) is another system for granting authorization to access resources in a virtual organization. In the VOMS system, the user is assigned membership of groups with roles and capabilities. This information is contained in the proxy certificates returned to the user. Interestingly, this project started by facing the difficulties of using grid-map files but does provide an automatic way of creating grid-map files. Another system that can create grid-map files locally is GUMS (Grid User Management System 2006). In GUMS, the grid-map file can be created statically or dynamically to jobs by the GUMS server.

Organizations will already have a local security system in place for their networks and computers, with which a grid security system may have to interface. One such system, created by MIT, is Kerberos, which provides a network authentication protocol. Kerberos uses tickets, which are electronic credentials used to verify your identity and provide specific access rights. Users first receive a ticket-granting ticket encrypted with their password. If they can decrypt this ticket, they have proved their identity and can obtain additional tickets for specific access rights. Kerberos has the single sign-on feature. For more information, see the Kerberos documentation (Kerberos: The Network Authentication Protocol, n.d.) The KX.509 project (KX.509: X.509 Certificates via Kerberos 2005) provides a means of creating X.509 certificates that are Kerberos-authenticated. These certificates are issued by a Kerberos-authenticated server (KCA). PKINIT is an Internet Engineering Task Force (IETF) Internet draft for authentication in Kerberos that allows a Kerberos ticket to be obtained using GSI credentials rather than a Kerberos password.

SAML (Security Assertions Markup Language) is an Organization for the Advancement of Structured Information Standards (OASIS) standard XML language for communicating user authentication and authorization information. SAML provides assertions that contain statements. These statements are grouped into authentication statements that indicate that the user has been authenticated, attribute statements used for making access control decisions, and authorization decision statements. SAML is a language for use in single sign-on authentication and authorization systems but is not an implementation. An example of a system using SAML is Shibboleth. Detailed information on SAML is given by Hughes and Maler (2005). More information on Shibboleth can be found at Shibboleth Project Web site (Shibboleth Project, n.d.).

RESOURCE MANAGEMENT

Data Management

One of the most challenging issues that has come up in recent years is the management of the large amounts

of data being collected by scientists. The challenges of managing large volumes of data are where to store it, how to classify it, what metadata does it need, how to transfer it, where to find data of interest, how to deal with replication, how to deal with distribution, etc. There are several tools included with the Globus Toolkit that can assist with dealing with data in particular for transferring files.

One component is GridFTP (Allcock et al. 2005). GridFTP is actually a protocol, although the Globus Toolkit has an implementation of GridFTP. The protocol builds on the FTP protocol. The extension includes security, reliability, striping, third-party transfers, partial file access, and parallel transfers. GSI security is used, which is PKI-based. Reliability is achieved by having the receiving server periodically send restart markers to the sending server. These markers indicate which bytes have been received so far. This allows the sending server to restart the transfer as necessary. Striping is when either the sending side, receiving side, or both are clusters sharing a parallel file system. Striping allows for each node in the cluster to send part of the file in parallel. GridFTP also supports parallel data transfer through the use of multiple TCP streams between pairs of hosts.

Third-party transfers are a very useful feature, in which a user can initiate from one machine a file transfer that takes place between two other machines. For example, a scientist may want to run a program on a supercomputer with data that currently resides in a data store on another server, but the scientist is currently using a laptop for access. Third-party transfer will allow the scientist to stage the file on the supercomputer without the need to transfer it to the local laptop, which may be impractical or even infeasible if the file is large. Partial file access allows one to transfer only part of a file by providing an offset and total number of bytes desired. This is useful for file caching.

The GridFTP protocol is a low-level file transport protocol. It has very nice and useful features, but should be viewed as a tool on which higher-level tools should be developed. Reliable file transfer (RFT) (Chervenak et al., 2004) is a WSRF-compliant Web service for the transfer of files. Since it makes use of GridFTP, many of the features of GridFTP are available through RFT, such as GSI security, reliability, third-party transfers, and parallel streams. RFT also allows for file deletion and third-party file and directory transfers. RFT extends the reliability of GridFTP by using a PostgreSQL database to store restart markers. These restart markers are used as checkpoints and will allow RFT to continue the file transfer after server, network, container, or file system failures. The RFT Resource is implemented as a Persistent-Resource, which allows RFT to restart file transfers even after the Web services container is restarted. RFT is a very useful Web service for data management. Its primary contribution is its reliability. Although it is still fairly low-level, most higher-level tools should make use of RFT to take advantage of the security and reliability.

Once a file is transferred between hosts (either FTP, SFTP, GridFTP, or RFT) then there is an automatic duplication of that file. Often, the new copy is a temporary file and will be destroyed in short order. Other times, the file persists. One might view this as wasted space. However, duplication can also be useful. If a scientist transfers

a file from a data store to a supercomputer and another scientist needs the same file for another computation on the same machine, then the file would not need to be transferred twice. More likely, there may be a copy of a desired file on a file system that is more local than the file's source. Transferring the file from the local file system will likely be faster.

Replica location service (RLS) (Cai, Chervenak, and Frank 2004) attempts to make these scenarios possible by creating a distributed registry of file replicas. RLS introduces the terms *logical file name*, which is a unique identifier associated with the file contents, and *physical file name*, which refers to an actual file on an actual file system. An RLS deployment consists of at least one local replica catalog (LRC), which stores the logical to physical file name mappings. Clients can query this catalog as well as publish newly created files.

The RLS registry may be distributed, which allows for scalability as well as reliability against a single server crash. For a distributed configuration, RLS uses one or more replica location index (RLI) nodes, which collect logical to physical file name mappings from one or more LRCs. Figure 6 shows such a configuration. When a client queries the RLI, the RLI provides it with a list of LRCs where it believes the desired mappings exist. The client would then need to query those LRCs for the physical locations of the desired file replica. Mappings are sent from the LRCs to the RLIs using a soft-state update protocol. This allows for the mappings to be transferred only periodically. Since the mappings have timeouts associated with them, a RLI that is brought back online after a failure will have its mapping restored.

The data replication service (DRS) (Chervenak et al. 2005) is a WSRF-compliant Web service built on top of RFT and RLS. It attempts to make sure that a set of files is available on a particular file system. It will query RLS to find the desired files. Then it will use RFT to carry out

the transfer. After the files have been transferred, DRS will register the duplicates with RLS. DRS is a very powerful tool that provides a nice abstraction of data management to the user. There does not seem to be much use of this level of abstraction in Grid applications yet. However, tools like DRS will be necessary components as the Grid resources and number of users grow.

Job Schedulers and Resource Managers

The Globus Toolkit does not have schedulers built in (with the exception of a “fork” scheduler, which is hardly a scheduler). Schedulers are provided by third-party vendors. There are two levels of scheduling in the Globus environment: local scheduling, which Globus uses to carry out the execution of a job on a local resource, and metascheduling, which is a higher level than the grid middleware.

The basic scheduling mechanism that ships with Globus as the default scheduler is Fork. Fork simply forks a new process in which to run the job. Fork does not provide many features other than the ability to start a job and monitor its status. It is meant only as a tool to allow a server with Globus to function out of the box. Users desiring more functionality should use one of the many other third-party schedulers that provide a much richer set of features.

There are many scheduling packages available, and most of them provide similar functionality. A few of the more popular or well-known scheduling systems are Portable Batch System (PBS) (Altair Grid Technologies 2006), Sun Grid Engine (SGE) (Sun N1 Grid Engine 6 2006), Platform Load Sharing Facility (LSF) (Platform 2006), Maui, and Torque, all of which provide the basics mechanics of scheduling and executing batch jobs on a variety of execution servers. They have similar functionality, such as allowing the user to specify scheduling algorithms, job priority, job interdependency, and automatic file staging.

Figure 6: Replica location service configuration

The first implementation of PBS is the OpenPBS by NASA. The PBSPRO (by Altair) provides some additional features such as a graphical user interface (GUI), security and access control lists, job accounting, desktop idle-cycle harvesting, automatic load-leveling, username mapping, and parallel job support by supporting libraries such as the Message Passing Interface (MPI), Parallel Virtual Machine (PVM), and High Performance Fortran (HPF). SGE also provides a GUI, checkpointing, and support for parallel jobs.

Condor (Thain, Tannenbaum, and Livny 2003) is a scheduler that is designed to allow users to make use of idle machines. One of the benefits of Condor is that the source code of the job does not need to be modified. However, if the source code can be recompiled and linked with the Condor libraries, then the job can have the benefit of being checkpointed. Checkpointing allows a job to be restarted in mid-execution. The purpose of this is to allow a job to recover after a server failure. Condor also intercepts the system calls of the job and executes them on the local machine (where the job was submitted). What this accomplishes is to allow data to reside on a separate machine, which is less intrusive on the remote machine. Furthermore, the user does not need to have an account on the remote machine.

Nimrod (Abramson et al. 1995) is a tool that controls the distributed execution of parameter-sweep applications. In parameter-sweep applications, the same program will be executed many times on a slightly different set of input parameters each time. These types of applications are very well suited for distributed computing, as each execution can be run independently. Nimrod is a tool that makes it easy to set up and control the execution of parameter-sweep applications.

Metaschedulers

Metaschedulers are systems that are designed to work at a very high level, on top of existing grid and scheduling middleware, scheduling jobs between sites. Since grids often include systems with heterogeneous resources, they will also likely have a variety of local schedulers. Currently available metaschedulers include Community Scheduler Framework (CSF 2005), Nimrod/G (Buyya, Abramson, and Giddy 2001), and Condor-G (Thain, Tannenbaum, and Livny 2003). These metaschedulers provide similar functionality, such as the ability to submit jobs, define scheduling policies, and make reservations for resources. The resources themselves may use different local schedulers, such as Fork, PBS, LSF, SGE, Nimrod, or Condor. Metaschedulers make use of the Globus Toolkit and can take advantage of the many features provided through the toolkit, such as authentication through GSI, resource discovery through GDS (grid data service), job execution and scheduling through GRAM, and data management through RLS and DRS.

USER INTERFACE AND WORKFLOW MANAGEMENT

Most examples of Grids use a batch-mode processing model. Unfortunately, this has been the mode of operation

since the beginning of the computer age. For Grids to gain widespread acceptance and use, they will eventually need to become as easy to use as, say, the World Wide Web. As the World Wide Web and the browser propelled the use of the Internet by scientists and the general population and make the Internet a household name, a similar user-friendly environment will be necessary to propel the use of grids by the general population. There are two main thrusts in the area of graphical and intuitive user interfaces for grids: portals and workflow editors, which are discussed below.

Portals

Grid portals are browser-based dynamic content environments that provide a single sign-on interface to grids. Portals are similar to servlets, in that they are Java-based components that generate dynamic content, usually in the form of HTML, extensible HTML (XHTML), or wireless markup language (WML), which is displayed in a browser. Portals are made up of Java Web-based components called "portlets," which generate the content and are managed in a portal container. Portals also use the client/server relationship as with servlets.

Of course, the purpose of portals is to provide an interface to grids. Although the architecture of portals is similar to servlets, there are a number of differences, which necessitates a separate designation for portals. The most salient of these differences include: portlets only need to generate content fragments as opposed to complete documents, portlets are not associated with a URL, there can be many instances of a portlet within a portal page, portlets can maintain persistent data, and portlets have access to and require access to the user's profile data.

The JSR 168 Portlet Specification (JSR-000168 Portlet Specification 2003) defines a standard Java API for creating portlets. This is an important specification that will ensure the interoperability of portal containers produced by different vendors. Two well-known portal toolkits that will help users create portals that are JSR 168-compliant are open grid computing environments (OGCEs) (Gannon et al. 2003) and GridSphere (Novotny, Russell, and Wehrens 2004).

Workflow Editors

Workflow editors are another form of graphical user interfaces to Grids. Whereas portals allow the user to start, monitor, terminate, etc. a Grid application, workflow editors also allow users to run several interdependent applications and describe dependencies between the applications, coordinating the inputs and outputs of various Grid applications.

OGSA-DAI (Antonioletti, Atkinson, Baxter, et al. 2004; Antonioletti, Atkinson, Borley, et al. 2004) is an initiative to create middleware that makes accessing and integrating databases much easier. OGSA-DAI provides the mechanism through Web services to access a variety of database types, including relational databases, XML files, and flat files. The data that are extracted from databases can be transformed using extensible stylesheet language transformation (XSLT) or compressed using ZIP or GZIP,

then delivered to a variety of sinks. The sinks can be other OGSA-DAI services, URLs, FTP servers, GridFTP services, or simply files. Although OGSA-DAI comes with a GUI, it is intended to be middleware. OGSA-DAI is a very powerful tool that can be very helpful in building other tools, especially workflow editors.

GridNexus (Brown et al. 2006) is a workflow editor, which uses Ptolemy (Lee 2003) as its GUI to develop workflows that are described in an XML scripting language called JXPL. The GUI allows users to create actors, or modules that can function as generic clients to Web services and grid services. GridNexus also has an actor that functions as a generic client to GRAM for the submission of a batch job.

Figure 7 shows a workflow in GridNexus that uses a Web service and a grid service. The actors are configured by providing the WSDL of the Web service or AddressingLocator class of the grid service. Once the actor is configured, its input and output ports are created to match the inputs and outputs of the service. The user is

then able to call these services simply by providing input to one of the ports.

Although the functionality of this workflow is very simple, it demonstrates how the output of one actor becomes the input of another. Given that these actors represent calls to remote services, chaining together these services without the use of a workflow editor is a rather tedious process. Consider the workflow shown in Figure 8. This workflow implements a computational chemistry application in which a user wishes to use a local molecule file as input, convert it to an intermediate format, manipulate it using an interactive program, manipulate it again using a local program, run it through a Grid service that performs analysis, then save the result of that to the local machine. The steps necessary to perform this work without the use of a workflow editor is very tedious and prone to error.

The GRAM client (GridExec actor) allows the user to run a job on a remote machine. The user can also perform file staging with this actor. If the file staging is not a viable option, then there are also actors to perform these

Figure 7: Simple GridNexus workflow

Figure 8: Chemistry application using GridNexus

functions through the use of GridFTP or SFTP (SSH file transfer protocol). GridNexus also has a set of actors to interface with OGSA-DAI.

Kepler (Altintas et al. 2005) is another workflow editor that is based on Ptolemy. One significant difference between Kepler and GridNexus is that Kepler is an extension of the Ptolemy system, whereas GridNexus uses Ptolemy to produce scripts in JXPL, and the JXPL interpreter provides the functionality. The Kepler approach has the advantage of leveraging the functionality of the already mature Ptolemy implementation. The GridNexus approach requires an additional language and corresponding interpreter. However, the advantage of using a separate language is that it separates the execution from the GUI, allowing various parts of the workflow execution to migrate to other processors.

Kepler has another component that provides a useful advantage. The library GriddleS provides a rich set of interprocess communication facilities. The GriddleS library traps input/output system calls and redirects them to services that can perform the desired operation on a local file, remote file, replicated file, or shared buffer. Access to remote files is available through GridFTP, SRB (storage resource broker), or SCP (secure copy). The shared buffer option allows for interprocess pipelined communication.

Although workflow editors make the coordination of tasks and the inputs and outputs between those tasks easier to manage, it is a challenge to adapt legacy code to a workflow actor. There are no standards with respect to how existing applications expect input or how they should produce output. Some applications expect their input to be on the command line, in input files, from standard input, or in specially named files. Furthermore, file systems may have substantially different configurations. For example, large data files may need to be placed on scratch files systems with large capacity but local to individual processors of a cluster. Dealing with the differences of these file systems is a formidable challenge for a workflow editor.

CONCLUSION

This chapter has described the components of a grid infrastructure, starting with Web services, which is an underlying technology used in grid software such as Globus. Web service technology is an attractive technology because of its language- and machine-neutral interface. Web services use XML. The SOAP protocol is used to carry information using XML. The XML language WSDL is used to describe the Web service interface in a language- and machine-neutral manner. The concept of a Web service container is also described in this chapter. With that introduction, we then move onto Grid computing standards and how Web services are used in Grid computing, in particular WSRF. Grid security is described in some detail, including ways to arrange certificate authorities. Then, we describe components for resource management and schedulers. The final section describes workflow management components. This chapter is intended to give the reader an understanding of the various fundamental components needed to create a Grid computing infrastructure.

GLOSSARY

Credentials: A certificate and corresponding private key collectively. There can be user credentials, proxy credentials, host credentials, etc. However, the private key is available only to the owner, and the word *credentials* can be used quite loosely to not include the private key.

Globus: A project that provided reference implementations for Grid computing standards. Provides a toolkit of component parts, which can be used separately or, more likely, collectively for creating a Grid infrastructure.

Grid-Map File: A form of access control list for authorization. The grid-map file is a file maintained at the site that holds the list of users' distinguished names (as given on their certificates) and their corresponding local account names.

Grid Portals: Browser-based dynamic-content environments that provide a single sign-on interface to grids.

Open Grid Services Architecture (OGSA): Defines standard mechanisms for creating, naming, and discovering services in a grid computing environment. Deals with architectural issues to make interoperable grid services.

Proxy Certificates: Certificates used in Grid computing to allow delegation of the user's authority. Proxy certificates are signed by the user (or the proxy entities themselves in a chain of trust) rather than by the certificate authority.

Public Key Infrastructure (PKI): A security arrangement that uses public key cryptography. In this form of cryptography, two keys (numbers) are used, one to encrypt the data and another (the key) to decrypt the data. One key, called the "public key," is made known to everyone, whereas the other key, called the "private key," is known only to the owner.

SOAP: A communication protocol for passing XML documents, standardized by the W3C organization (World Wide Web Consortium). Originally, SOAP stood for simple object access protocol. However, the spelled-out version has since been dropped because this name was not accurate; specifically the protocol does not involve object access.

Uniform Resource Locator (URL): A string of characters used to identify a resource on the World Wide Web; it includes the protocol used to access the resource. For example, www.cs.uncc.edu is the URL of the main computer science page at UNC-C, to be accessed by hypertext transfer protocol (HTTP).

Web Service: A software component designed to provide specific operations ("services") that are accessible using standard Internet technology. A Web service is usually addressed by a uniform resource locator (URL).

Web Services Resource Framework (WSRF): A set of specifications that present a way of representing state while still using the basic WSDL for Web services applications. Instead of modifying the WSDL to handle state, the state is embodied in a separate resource.

Web Service Definition Language (WSDL): An XML standard for formally describing a Web service—what it does, how it is accessed, etc. The standard is published by the World Wide Web Consortium (W3C).

Workflow Editor: A graphical user interface to grids that allow the user to run several interdependent applications and describe dependencies between the applications, coordinating the inputs and outputs of various grid applications.

WS-Resource: The combination of a Web service and resource in the Web Services Resource Framework (WSRF).

XML (Extensible Mark-up Language): A standard mark-up language developed to represent textual information in a structured manner that could be read and interpreted by a computer. XML is a foundation for Web services, and Web services now forms the basis of Grid computing.

INTRODUCTION

Many computationally intensive applications in science, engineering, and business cannot be solved in a reasonable length of time on any single-processor machine. Parallel processing is an approach that might be considered instead—that is by dividing a large and complex computational problem into subtasks and distributing these subtasks across several processors. Each processor works on the assigned subtask concurrently. The total execution time can therefore be reduced to an acceptable level.

Parallel processing is traditionally performed on supercomputers that may have hundreds or thousands of processors as well as a large capacity for data storage. Prior to the late 1980s, the development of supercomputers was typically accomplished with custom-designed systems consisting of proprietary hardware and software. Companies such as IBM, Amdahl, Thinking Machines, and Cray developed sophisticated systems that took years to bring to market and cost tens of millions of dollars. Applications that executed on supercomputers were normally written using proprietary programming libraries and were generally not portable to other platforms. Furthermore, supercomputers are generally difficult to gain access to, and may not represent the most cost-effective solution for certain types of problem.

The concept of “connecting a collection of distinct computers together with a network” or simply a “commodity cluster” as a unique platform for parallel processing began in the late 1980s. The primary driving force was the rapid advances of commodity off-the-shelf (COTS) hardware, and the shortening of the design cycle for these components made the design of custom hardware costly in comparison. That is, by the time a company designed and developed a supercomputer, the processor speed and its capability was outpaced by commodity components. In addition to the rapid increase in COTS hardware capability that led to increased cluster performance, software capability and portability increased rapidly during the 1990s. A number of software systems that were originally built as academic projects led to the development

of standard portable languages and new standard communication protocols for cluster computing.

This chapter provides a review of cluster-based systems, the various architectures, and the hardware and software components that have led to the growth in deployment, and it presents conclusions on the likely future of cluster-based computing. The aim of this chapter is to provide a high-level overview of clusters and the associated technologies and components. The chapter does not, however, present details of various cluster products and applications.

CLUSTER COMPUTING

Earning the nickname “a poor man’s supercomputer,” the capability of clusters increased rapidly during the 1990s. To illustrate this rapid increase, the Wiglaf Beowulf cluster, composed of 16 Intel 80486 100-MHz processors and dual 10 megabits per second (Mbps) Ethernet networks, delivered a sustained rate of 19 mega floating-point operations per second (MFLOP/s) on the N-body problem in 1995. By the end of 1996, clusters were reported to reach a sustained performance of 1 GFLOP/s (The Beowulf Project 2004). In 1997, NASA researchers at Goddard Space Flight Center further demonstrated a sustained computational rate of 10.1 GFLOP/s, using a cluster composed of 199 200-MHz Pentium Pro processors interconnected with Fast Ethernet (Merkey 2004). In 1998, a four-node Sun Enterprise cluster achieved a world record of 1 terabyte Transaction Processing Performance Council (TPC) (*Sun and Informix set new data warehousing record*, 1998) benchmark result, outperforming existing results set by proprietary solutions with significantly less hardware. In 1999, Oracle and Compaq announced a TPC-C world record (*Compaq sets Windows/NT performance record*, 2000) for Windows NT on a six-node cluster of Compaq ProLiant 6500 servers running the Oracle8 database. A cluster using the Hewlett-Packard Alpha family of processors was reported in 2000 to achieve a sustained performance level of 507 GFLOP/s. This was fast enough to earn the rank

of thirty-first on the list of the world's 500 most powerful computers (*The Top500 Supercomputer sites*, 1993).

Clusters have continued to achieve significant ranking in the Top 500 Supercomputer list since 2000. In 2002, the top five supercomputers included Earth Simulator (35.86 TFLOP/s, 5120 processors), the ASCI Q systems (7.72 TFLOP/s, 4096 processors), the ASCI White (7.23 TFLOP/s, 8192 processors), and the MCR Linux Cluster (5.69 TFLOP/s, 2304 Xeon 2.4 GHz processors). Indeed, 72% of the top 500 machines listed in November 2005 are based on clusters that number between 400 and 8000 processors, connected by high-speed networks such as Gigabit Ethernet, Myrinet, or InfiniBand technology.

Cluster technologies have evolved from purely research efforts and demonstrators into a widely adopted solution for technical computing, meeting the needs of high-performance, high availability, and production-quality environments. In addition to hardware advances, cluster deployment and management tools and fast communication libraries have continuously evolved throughout the past decade. Cluster tools such as OSCAR (2000) and ROCKS (2000), using freely distributed open source Linux operating system, scheduling software, and tools, greatly eases the deployment and administration processes. Communication libraries such as the Message Passing Interface (MPI 1993) and Parallel Virtual Machine (PVM 1990) have become the leading message-passing systems for parallel applications. The development of new algorithms that are latency-tolerant has also allowed complicated applications to be executed effectively in cluster environments. Consequently, clusters have found a much wider range of application than was originally envisaged.

The success of cluster computing is the result of many concurrent threads of research and development. For instance, the Institute of Electrical & Electronics Engineers (IEEE) Technical Committee on Scalable Computing (TCSC), (IEEE Task Force on Cluster Computing 1999), previously known as the IEEE Computer Society Task Force on Cluster Computing (TFCC) (IEEE Technical Committee on Supercomputing Application 2004), which was founded in December 1998, continues to promote cluster computing as a collaborative effort between

industry and academics. Today, numerous businesses, universities, and government organizations rely on clusters to perform their mission-critical computations.

The remainder of this chapter describes the various cluster architectures, surveys cluster hardware and software components, and presents conclusions on the likely future of cluster computing.

CLUSTER ARCHITECTURES

The TCSC has defined a cluster as a type of parallel or distributed system that consists of a collection of interconnected whole computers used as a single, unified computing resource, where “whole computer” is meant to indicate a normal, whole computer system that can be used on its own: processor(s), memory, input/output (I/O), operating system (OS), software subsystems, and applications (*IEEF TFCC Newsletter* 1999). Despite the success of cluster computing, the term *cluster* is still being misused today. *Cluster* means different things to different people, primarily because of their assumption of the underlying system architectures. Dongarra et al. (2005) clarified the term *cluster* and asserted that it should not be used casually to imply all parallel computer architectures, but rather it should be used to refer to “a specific class of such system.”

To comprehend the basics concept of cluster computing, we describe a generic architecture through which nodes can be connected to provide aggregated processing and storage resources. In general, a generic cluster architecture is composed of three major components (see Figure 1): the computing nodes, the dedicated interconnection network, and a suite of cluster-aware software. Each node can be a single or multi-processor computer, such as PC, workstation, or symmetric multi-processor (SMP) server, equipped with its own memory, I/O devices, and operating system. The nodes are interconnected by a local area network (LAN). Various network topologies can be realized to speed up data exchange between applications, which are running on different nodes. The speed of network interconnects is normally characterized by two parameters: bandwidth and latency. Bandwidth indicates the amount of data that can be transferred through

Figure 1: A generic cluster architecture

a particular network connection within a given time unit; latency is the time it takes for a networking device to process a data frame. The optimal choice of the network technology as well as its topology is generally dictated by the application's demand of speed and volume of data exchanged.

On each computing node, various operating systems, such as Linux, Solaris, and Windows, can be used to provide system services and to manage local resources. In addition, a set of software components is installed on each node. In general, this set of software can be categorized into resource management and application programming tools. Resource management tools, shown as cluster middleware in Figure 1, provide system configuration (including tools for initial installation and configuration), administration, scheduling, and allocation of both hardware and software resources as applied to user workloads. Programming tools, such as compilers, language, libraries, and debuggers, provide an environment for users to develop their parallel and distributed applications. We will describe some cluster hardware and software components in more detail in the section on Cluster Components and Technologies.

In general, a cluster's architecture is normally configured for a particular application type. The terms such as *Beowulf*, *Constellation*, *Super-cluster*, and *Meta-cluster* are commonly found in the literature to indicate a particular configuration of a cluster. In the following sections, we will describe three popular cluster configurations: high availability, high performance, and high throughput. It is worth noting that a hybrid of these configurations is used in some cases to promote a highly reliable system, characterized by high performance and balanced workloads.

High Availability

High-availability (HA) clusters are those that continue to perform critical tasks in the presence of system failures. Commodity clusters are ideal for implementing HA systems, as commodity products are easily replicated. By the late 1990s, virtually all major hardware and software vendors offered HA products based on clusters. Many applications—Web servers, e-commerce servers, and database applications, in particular—can benefit from systems that offer high availability, since these can prevent the loss of data and services in the event of a failure.

High availability depends on more than a redundant set of hardware that can take over tasks if a hardware component fails. For systems to be highly available there must be a coordinated set of software utilities that can detect failure, ensure data correctness, and manage the redistribution of tasks if necessary. Freely distributed software projects are available today for enabling HA clusters.

The High Availability Linux project (1999) (HA-Linux) began with the goal of developing extensions to Linux cluster software that will provide reliability, availability, and serviceability. The project is far-reaching in its goals to provide high availability. For example, resources in HA-Linux are anything that can move from one machine to another. Resources include file systems, processes, Internet protocol (IP) addresses, and other items, and the goal

is for these to be able to be quickly migrated across a cluster in the event that a failure is detected.

The other software project that focuses on high-availability is the High Availability OSCAR Project (2002) (HA-OSCAR). HA-OSCAR is based on OSCAR, a software package designed to simplify cluster installation (see the section on Cluster Management Tools, below). HA-OSCAR introduces several enhancements and new features, mainly in the areas of availability, scalability, and security. The features included in the initial release are head node redundancy and self-recovery for hardware, service, and application outages.

High Performance

High-performance computing (HPC) clusters are optimized for workloads, which require jobs or processes running on the separate cluster nodes to communicate actively during a computation. These include computations for which intermediate results from one node's calculations will affect future calculations on other nodes. The advantage of using a HPC cluster is to reduce the total turnaround times on compute-intensive problems or when a problem is just too large to run on a single system.

One of the more popular HPC implementations is a cluster with nodes running Linux as the OS and free software to support parallelism. This configuration is often referred to as a "Beowulf cluster." Such clusters commonly run custom programs, which have been designed to exploit the parallelism available on HPC clusters. Many such programs use libraries such as MPI, which are specially designed for scientific applications executing on HPC systems.

Load Balancing

A load-balancing system allows the sharing of the processing load as evenly as possible across a cluster of computing nodes. The differentiating factor in this case is the lack of a single parallel program that runs across these nodes. Each node, in most cases, is an independent system running separate software. However, there is a common relationship between the nodes either in the form of direct communications between the nodes or through a central load-balancing server that controls each node's load. Although load-balancing systems are implemented primarily to improve response time, they commonly include high-availability features as well.

As an example, network service load balancing is a process of examining the incoming requests to a cluster and distributing the requests to each of the nodes for processing as appropriate. Often a network server takes in too many service requests to be able to process them quickly enough, and thus the requests need to be sent to the corresponding applications on other nodes. This can be optimized according to the different resources available on each node or the particular environment of the network. This type of load sharing is best for network applications such as Web or file transfer protocol (FTP) servers.

In general, load-balancing clusters can provide both high availability and scalability for important computer applications, such as those in the business, medical,

and scientific arenas. However, the difficulty in accurately scheduling loads across processes should not be underestimated. Many approaches try to equalize the number of processes on the nodes or equalize their task queue lengths. Load balancing becomes more complicated if the system consists of heterogeneous nodes—for example, faster and slower processors, different amounts of memory, and different numbers of CPUs per node (SMP or multi-core). Similarly, most real applications and tasks in the system are heterogeneous. They consume different amounts of resources—i.e., they execute for short or long times and use different percentages of the CPU time. In addition, the arrival of tasks is not coordinated or planned, so load balancing has to cope with changing, unpredictable load profiles. Another complication is that parallel applications are not just sets of independent tasks, but tasks that can have dependencies on each other for proper execution. Other effects, like the overhead associated with context switching or paging delays can severely influence a system's performance. Consequently, load balancing should be adaptive—i.e., it should identify the currently important performance factors, create estimations by profiling the system behavior, and find the trade-off between load-balancing overhead and improvement in the current load situation. With all these factors to take into account, constructing an efficient load-balancing cluster is far from a trivial exercise.

The use of clusters for load balancing is, however, a very attractive prospect. There are many commercial load-balancing systems available, including, the Moab Cluster Suite (2001) and the Maui Cluster Scheduler (2000). The Linux Virtual Server (1998) is another project that provides one of the commonly used free software packages for the Linux OS. The large-scale parallel nature of clusters offers a perfect setting for the distribution of work across their nodes. The disadvantage is that to get efficient sharing of the load, a lot of work has to be done to organize processes scheduling.

CLUSTER COMPONENTS AND TECHNOLOGIES

The continuous improvements of computer and network performance as well as the availability of standardized application programming interfaces (APIs) have allowed cluster computing to redefine the concept of high-performance computing and highly available systems. This section describes some of these hardware and software advances.

Hardware Components

Cluster Nodes

Each computing node of a cluster can be a single or multiple microprocessors or a multi-core system, equipped with its own memory, storage, and I/O devices.

Processors. Today's single microprocessor is almost as powerful as many of yesterday's supercomputers. Intel processors are the most commonly used in PC-based systems. Intel microprocessors offer excellent price for performance because of the economy produced by the high-volume sales. However, as these (and other)

microprocessors continue to become more complex, it is becoming harder for modern compilers to be able to generate efficient code. Other popular processors include AMD (2007), IBM Power 5 (1990), and Sun Ultra-SPARC (2005).

Multi-core processors are the next wave of microprocessors. A multi-core microprocessor combines two or more independent processors into a single package, often a single integrated circuit (IC). For example, a dual-core device contains only two independent microprocessors. In general, multi-core microprocessors allow a computing device to exhibit some form of thread-level parallelism (TLP) without including multiple microprocessors in separate physical packages. This form of TLP is often known as chip-level multiprocessing, or CMP. Some examples of multicore processors are Intel's dual-core Xeon processors, code-named Paxville and Dempsey (Intel Dual-Core Server Processors 2005), and AMD's dual-core Opteron, which was released in April 2005 (AMD Multi-Core Products 2005).

Memory. Originally, the memory installed in a PC was 640 KB, usually "hardwired" onto the motherboard. Typically, a PC today will be delivered with between 512 MB and 1 GB installed in slots, with each slot holding a dual in-line memory module (DIMM). The main difference between the traditional single in-line memory modules (SIMMs) and DIMMs is that SIMMs have a 32-bit data path, while DIMMs have a 64-bit data path. Computer systems can use various types of memory, including synchronous dynamic random access memory (SDRAM), double data rate (DDR) SDRAM, and Rambus DRAM (RDRAM).

Access to DRAM is slow compared with the speed of the processor. Typically, it takes up to two orders of magnitude more time than a single processor clock cycle. Caches are used to keep recently used blocks of data for very fast access if the CPU references a word from that block again. However, the fast memory used for a cache is relatively expensive, and cache control circuitry becomes more complex as the size of the cache grows. These limitations generally restrict the total size of a cache to between 8 KB and 2 MB.

System Bus. The initial PC bus (Advanced Technology [AT]), or now known as Industry Standard Architecture [ISA] bus [Industry SA Bus 2001]) was clocked at 5 MHz and was 8 bits wide. When first introduced, its abilities were well matched to the overall system. PCs are modular, and until recently, only the processor and memory were located on the motherboard. Other components were typically found on daughter cards, connected via the system bus. The performance of PCs has increased by several orders of magnitude since the introduction of the ISA bus. Consequently, the ISA bus became a bottleneck, limiting system capabilities.

The ISA bus was extended to be 16 bits wide and clocked in excess of 13 MHz. This, however, was not sufficient to meet the demands of contemporary CPUs, disk interfaces, and other peripherals. A group of PC manufacturers introduced the Video Electronics Standards Association (VESA) local bus (2001), a 32-bit bus that matched the system's clock speed. The VESA bus has now largely been superseded by the Intel-created PCI-bus (Peripheral

Component Interconnect [PCI] Local Bus 1993) that allows data transfer at 133 MB/s and is used inside Pentium-based PCs. PCI has been adopted for use in non-Intel-based platforms, such as the Digital AlphaServer range. The move toward a 64-bit bus was necessary to exploit the full power of Pentium processors and to make the memory architecture similar to that of a general-purpose UNIX workstation. This has further blurred the distinction between PCs and the UNIX workstation, as the I/O subsystem of a workstation is often built from commodity interfaces and interconnects.

The PCI Express (PCIe), introduced in 2004, is becoming the new backplane standard in personal computers. One driving force is that most of the new graphics cards from both ATI Technologies (2007) and NVIDIA (1995) use PCIe. In particular, NVIDIA uses the high-speed data transfer of PCIe for its newly developed scalable link interface (SLI) technology, which allows two graphics cards of the exact same chipset and model number to be run at the same time, allowing increased performance. ATI Technologies has also developed a multi-core graphic-processing unit (GPU) system based on PCIe called Crossfire (ATI Crossfire 2006).

Storage. The two disk interfaces found in personal computers are ATA (Advanced Technology Attachment) (ATA-ATAPI 2006) and SCSI (Small Computer System Interface) (SCSI Trade Association 2003) for connecting storage devices such as hard disks and CD-ROM drives.

ATA is more commonly known as IDE (integrated device electronics) or enhanced IDE (EIDE). With the introduction of serial ATA (SATA or S-ATA) in 2003, ATA was retrospectively renamed parallel ATA (PATA) to distinguish it from serial ATA. SATA is a computer bus technology primarily designed for the transfer of data to and from a hard disk. The first-generation SATA interfaces, also known as SATA/150, run at 1.5 GHz. SATA uses 8 B/10 B encoding at the physical layer. This encoding scheme has an efficiency of 80%, resulting in an actual data transfer rate of 1.2 GB per second (Gbps), or 150 MB/s. SATA-II interfaces were introduced in 2004 with clock rates reaching 3.0 GHz. SATA-II can deliver a maximum throughput of 300 MB/s and is both forward- and backward-compatible with SATA. This enables SATA hardware to interface with SATA II ports and vice versa. However, some systems, which do not support SATA speed autonegotiation, may have to manually limit their drive's speed to 150 MB/s with the use of a jumper for a 300 MB/s drive.

The other disk interface is small computer serial interface (SCSI). SCSI is most commonly used for connecting a wide range of other devices, including scanners, printers, CD recorders, and DVD drives. In fact, the entire SCSI standard promotes device independence, which means that theoretically SCSI can be used with any type of computer hardware. There are three SCSI standards, SCSI-1, SCSI-2, and SCSI-3.

SCSI-1 features an 8-bit parallel bus (with parity), running asynchronously at 3.5 MB/s or 5 MB/s in synchronous mode. SCSI-2 standard has two variants: fast SCSI and wide SCSI. Fast SCSI doubled the maximum transfer rate to 10 MB/s and wide SCSI doubled the bus width to 16 bits, which enables the transfer rate of 20 MB/s. However, these improvements came at the minor cost of a

reduced maximum cable length to 3 ms. SCSI-2 also specified a 32-bit version of wide SCSI, which used two 16-bit cables per bus; this was largely ignored by SCSI device makers because it was expensive and unnecessary, and it was officially retired in SCSI-3. SCSI-3 also has two variants: ultra SCSI and ultra wide SCSI interface. Ultra SCSI is capable of a peak transfer rate of about 20 MB/s in asynchronous and ultra wide SCSI is capable of 40 MB/s. A SCSI interface may contain up to sixteen devices. For similar sizes, SCSI disks tend to outperform ATA drives; however, ATA has a significant price advantage.

Cluster Interconnect

Cluster nodes are interconnected by a network that is based on local area network (LAN) or system area network (SAN) technologies. Generally, the nodes and the interconnection network are based on one of the following technologies using Ethernet, Fast Ethernet, Gigabit Ethernet, Myrinet, scalable coherent interface (SCI), Quadrics Network (QsNet), InfiniBand communication fabric, ATM, and Fibre Channel, which are discussed below.

Ethernet. Ethernet (Spurgeon 2000; TechFest Ethernet Technical Summary 1999) has been, and continues to be, the most widely used technology for local area networking. Standard Ethernet transmits at 10 Mbps and has a large installation base. However, this bandwidth is no longer sufficient for use in environments in which users are transferring large quantities of data. Standard Ethernet cannot be used seriously as the basis for cluster computing since its bandwidth and latency are not balanced compared with the computational power of the computers now available.

Fast Ethernet. An improved version of Ethernet, commonly known as Fast Ethernet (TechFest Ethernet Technical Summary 1999), provides 100 Mbps bandwidth and is designed to provide an upgrade path for existing Ethernet installations. Both standard and Fast Ethernet are based on the concept of a collision domain. Within a collision domain, the communication channel is shared so that only one node can send at a time. If another node tries to send at the same time, then a collision occurs, both messages are garbled, and both nodes retry their communication after a random waiting period. With a shared Ethernet or Fast Ethernet hub, all nodes share the same collision domain and only one node on the network can send at a time. With a switched hub, each node may be on a different collision domain, depending on the manufacturer's specifications. In this case, two nodes can send at the same time as long as they are not both sending to the same receiver. In general, all switched networks, not just Ethernet networks, have this capability. For cluster computing, switches are preferred, since the ability for more than one node to send at the same time can greatly improve overall performance.

Gigabit Ethernet. Gigabit Ethernet (TechFest Ethernet Technical Summary 1999; Baker and Scott 2000) products, except for the lowest-end hubs, are based on high-speed point-to-point switches in which each node is in its own separate collision domain. Gigabit Ethernet

transmits signals at 1 Gbps. However, because of the encoding required at high speeds, Gigabit Ethernet has an effective user data rate of approximately 800 Mbps. Gigabit Ethernet products may have additional distance and wiring constraints over Fast Ethernet products because of the physical nature of sending high-speed signals. Currently, because of the speed of the processor, a single computer with a 32-bit bus can transmit data onto a network faster than Ethernet bandwidth, but somewhat slower than Fast Ethernet bandwidth.

10-Gigabit Ethernet. 10 Gigabit Ethernet (IEEE P802.3ae 10Gb/s Ethernet Task Force 2003) is the next generation in the Ethernet series. Consequently, 10-Gigabit Ethernet inherits all the advantages and disadvantages of previous Ethernet implementations. The primary advantages include interoperability with previous Ethernet generations, wide portability, and a ubiquitous interface (TCP/IP). The primary disadvantages have always been its relatively high latency and CPU load, as well as its expensive switches.

Standard and Fast Ethernet products are affordable and provide adequate capacity and latency for many cluster-computing applications. Most new computers today come with a built-in Fast and Gigabit Ethernet adapter. Gigabit Ethernet products generally cost less than other gigabit networking products, such as Myrinet and InfiniBand. Some Gigabit Ethernet switches are now offering 10-gigabit uplink ports essentially at the cost of installing the optics that is making it somewhat more practical to trunk multiple Gigabit Ethernet switches together.

Myrinet. Myrinet was one of the first interconnect technologies designed for cluster computing. Myrinet is a 1.28-Gbps full duplex network supplied by Myricom (Boden et al. 1995; Myricom 1994). It was used in the Berkeley Network of Workstations (NOW) (Anderson, Culler, and Patterson 1995) cluster and many other academic clusters. Myrinet uses low-latency cut-through routing switches, which simplify network setup and offer fault tolerance by automatically mapping the network configuration. Myrinet has a programmable on-board processor that allows for experimentation with communication protocols. Myrinet offers a native implementation of virtual interface architecture (VIA), as well as supporting the Message Passing Interface Chameleon (MPICH) implementation of MPI directly. There are Myrinet drivers for many operating systems, including Linux, Solaris, and Windows.

Myrinet is expensive as compared with Ethernet products. However, Myrinet is designed to be scalable, and its low latency, high bandwidth, and programmability make it competitive for cluster computing. Currently, Myrinet hardware uses a 2-Gbps link speed with PCI-X based network interface cards (NICs) providing one or two optical links. The dual-port NIC virtualizes the two ports to provide an effective 4-Gbps channel. The downside to the two-port NIC is cost—both the cost of the NIC and the extra switch port it requires.

Myricom announced its Myri-10G in mid-2005 (*Myricom Rolls Out 10-Gigabit Solutions* 2005). Myri-10G essentially extends Myrinet's architectural and performance advantages to 10-Gigabit speeds while also providing full interoperability with 10-Gigabit Ethernet.

Scalable Coherent Interface. Scalable coherent interface (SCI) (Gustavson 1992) was also one of the first interconnection technologies to be developed as a standard specifically for the purposes of cluster computing. The IEEE 1596 standard for SCI was published in 1992 and specifies the physical and data-link layers of the network as well as higher layers for distributed shared memory across a network. Since the layers are independent, it has been possible for many commercial products to be developed using the lower layers of SCI only. At the physical and data-link layers, SCI is a point-to-point architecture with small packet sizes. The standard defines 1-Gbps serial fiber-optic links and 1-Gbps parallel copper links. Dolphin Interconnect Solutions (1999) currently produces SCI adapter cards for the Sun SPARC SBus and PCI-based systems. At higher layers, SCI defines a directory-based cache-coherence scheme. Whenever a load or store occurs at a remote location that results in a cache miss, the cache controller accesses remote memory and data via SCI. The data are fetched to the cache with a delay on the order of a few microseconds, and then the processor continues execution. Message passing is also supported by a compatible subset of the SCI that does not invoke SCI cache-coherency protocols. Although SCI supports distributed shared memory, which programmers find appealing, the cost of a remote access is hidden to programmers so that optimization of applications is difficult. In addition, its scalability is constrained by the current generation of switches, and its components are expensive.

Quadrics. The Quadrics QSNET network (Petrini et al. 2002; Quadrics 1996) has been known mostly as a premium interconnect choice on high-end systems such as the Compaq AlphaServer SC. On systems such as the SC, the nodes tend to be larger SMPs with a higher per-node cost than the typical cluster. Consequently, the premium cost of Quadrics has posed less of a problem. Indeed some systems are configured with dual Quadrics NICs to further increase performance and to get around the performance limitation of a single PCI slot.

The QSNET system consists of intelligent NICs with an on-board I/O processor connected via copper cables (up to 10 m) to eight port switch chips arranged in a fat tree. Quadrics has released an updated version of their interconnect called QSNet II based on ELAN4 ASICs. Along with the new NICs, Quadrics has introduced new smaller switches, which has brought down the entry point substantially. In addition, the limit on the total port count has been increased to 4096 from the original 1024.

InfiniBand. InfiniBand (InfiniBand Trade Association 1999; Intel 2007) has received a great deal of attention over the past few years. InfiniBand was designed by an industry consortium to provide high-bandwidth communications for a wide range of purposes, which range from a low-level system bus to a general-purpose interconnect to be used for storage as well as internode communications.

The basic InfiniBand link speed is 2.5 Gbps (known as a 1X link). However, the links are designed to be bonded into higher bandwidth connections with four-link channels (a 4X link) providing 10 Gbps and twelve-link

channels (12X links) providing 30 Gbps. Current InfiniBand implementations are available as PCI-X-based NICs and 8- or 24-port switch chips using 4X (10 Gbps) links. The switch chips can be configured for other link speeds as well including 12X links. This makes switch aggregation somewhat easier, since you can configure a switch with twelve 4X links to connect to nodes and four 12X links to connect to other switches.

Current InfiniBand pricing is enjoying the benefits of aggressive venture capital funding while the various vendors attempt to define their market. Thus, there are a variety of vendors competing with slightly different NICs and switches, even though the core silicon in most current implementations is from Mellanox (1999).

ATM. ATM, or asynchronous transfer mode (The ATM Forum 2000), is an international network standard that grew out of the needs of the telecommunications industry. ATM is designed around the concept of cells, or small, fixed-sized packets. ATM is a switch-based technology that uses the idea of virtual circuits to deliver a connection-oriented service. ATM offers several classes of data delivery. Some classes are designed for voice and video communication, which require real-time guarantees on data delivery rates. Because of the recent consolidation of many telecommunications industry and Internet services, ATM is increasingly being used as a backbone technology in many organizations. Although ATM products offer high bandwidth, in comparison to other similar technologies, it is relatively expensive.

Fibre Channel. Fibre Channel (Fibre Channel Industry Association 2004; Meggyesi 1994) is a set of standards that defines a high-performance data transport connection technology that can transport many kinds of data at speeds up to 1 Gbps through copper wire or fiber-optic cables. The Fibre Channel standard is defined in layers, beginning at the physical layer. Like the SCSI standard, the standard layers are independent, enabling many companies to produce networking and cluster products based on the lower layers only. Fibre Channel is flexible, and mapping protocols have been defined that enable higher-level protocols, such as SCSI, IP, ATM, and high-performance parallel interface (HIPPI), to be used over Fibre Channel connections. Currently, the most frequent use of Fibre Channel in clusters is for data storage devices. The high-performance network capacity of Fibre Channel can be combined with SCSI and other I/O bridges to create a network of storage devices, separate from the primary cluster interconnect. A network of this type is sometimes called a storage area network (SAN), and is an important subsystem of many commercial clusters. As Fibre Channel matures it may become more widely used as a general-purpose cluster interconnection technology.

Software Components

Operating Systems

In a cluster used for parallel computing, each node is a computer that runs its own copy of the operating system. The operating system has two main functions: first, it makes the computer hardware easier to use. It creates a

virtual machine that differs markedly from the real machine and hides these intricacies from the user. Second, it enables the system resources to be shared among many users.

The two most popular operating systems for PCs are Windows and UNIX—generally in the form of Linux. Unlike some earlier operating systems for PCs (e.g., DOS), Windows and Linux are both multi-tasking operating systems. A multi-tasking operating system allows multiple tasks to execute on a single-CPU machine at the same time. The tasks take turns using the CPU for a very short time period (called a quantum), often in a round-robin fashion. An advantage of this approach is that whenever a task needs to perform I/O or wait for an event to occur that does not require the use of the CPU, another task can be executing. For example, a user can edit a document while another document is printing in the background or while the compilation of a large program occurs. This capability can also be used to allow computation and communication to overlap in large parallel programs, so that the performance of a cluster is improved.

Linux. Linux (1994) is a UNIX-like operating system initially developed by Linus Torvalds, a Finnish undergraduate student in 1991–92. The original releases of Linux relied heavily on the Minix operating system. However, the efforts of a number of collaborating programmers have resulted in the development and implementation of a robust and reliable, portable operating system interface POSIX-compliant operating system.

Linux provides the features typically found in most UNIX implementations, such as preemptive multi-tasking, demand paged virtual memory, and multi-user and multi-processor support. Although Linux was initially developed by a single author, a large number of authors are now involved in its continuing development. Linux quality control is maintained by allowing kernel releases only from a single point. In addition, its availability via the Internet helps in getting fast feedback about bugs and other problems. The following are some advantages of using Linux:

- Linux runs on cheap x86 and Pentium-based platforms, yet offers the power and flexibility of UNIX.
- Linux is readily available on the Internet and can be downloaded without cost.
- It is relatively easy to fix bugs and improve system performance. Users can develop or optimize peripheral drivers that can easily be distributed to other users.

To provide a UNIX-like environment, a Linux distribution combines the Linux kernel with a set of software that is freely available, including GNU system/application software (GNU Operating System 1996) and X.org (Xfree86 Project 1992; X.Org Foundation 2004), a public domain X-server. Table 1 lists some of the most popular Linux distribution companies and groups.

Unfortunately, there is no definite answer to which distribution is more suitable or “better” for building a Linux cluster. Indeed, several well-written books on this topic have been published (Spector 2000; Gropp, Lusk, and

Sterling 2003; Sloan 2004). Generally, the choice comes down to three factors: technical support, ease of use, and licensing.

Microsoft Windows Server 2003. Microsoft Windows (2000) is a dominant operating system in the PC marketplace. Windows Server 2003, Compute Cluster Edition (Microsoft Windows Server System. 2007; Windows Compute Cluster Server 2003), released in early 2006, is designed for high-performance computing clusters. Windows Server 2003 is the successor of Windows 2000 Server that incorporates compatibility and other features from Windows XP. Windows Server 2003 includes compatibility modes to allow older applications to run with greater stability.

Cluster Management Tools

Cluster management is about monitoring and administering all the nodes in a cluster. It covers a wide range of functionality, such as resource monitoring, membership management, reliable group communication, and full-featured administration interfaces. As such, it is impossible to cover all aspects in this section of the chapter. The following areas form the basis of the management of cluster resources.

- **System Installation and Configuration**—The software addresses the means of assembling, installing, and configuring the necessary hardware and software components that make up the complete system. The challenge of implementing and maintaining common software images across nodes, especially for systems made up of hundreds of nodes requires sophisticated, effective, and easy-to-use tools. Examples are Scyld (1998), ROCKS (2000), and OSCAR (Open Source Cluster Application Resources 2000).
- **Job Scheduler and Management**—The placement of applications onto the distributed resources of commodity clusters requires tools to allocate the software components to the nodes and to schedule the timing of their operation. Task allocation can be performed at different levels of granularity, including jobs, transaction, processes, or tasks. Examples are such as OpenPBS (1995) and Maui Scheduler (2000).

Communication Protocols

Clusters originally used the same transmission control protocol/Internet protocol (TCP/IP) that has traditionally been used in local and wide area networks. However, these protocols were designed in the 1960s for networks that had comparatively low bandwidth and high error rates as compared with the newer, high-speed networks used to interconnect modern clusters. Consequently, the traditional protocols have high overhead and low-bandwidth compared with the transmission time on high-speed networks. The performance of the cluster is dependent on the availability of efficient communications, both for exchanging data between processes that execute on different processors, and for exchanging control and synchronization information. A number of academic projects in the mid-1990s addressed this issue. The influence of these academic projects prompted Compaq, Intel, and Microsoft (1997) to organize a consortium to promote the development of a standard for low-overhead communication within a cluster. Version 1.0 of the VIA (virtual interface architecture) standard was published by the consortium on December 16, 1997. By 1999, major commercial vendors of database applications, including Oracle and IBM, were modifying their applications to execute in a cluster environment using the virtual interface architecture.

The standard TCP/IP protocols and the de facto standard Berkeley Software Distribution (BSD) sockets API for TCP and user datagram protocol (UDP) were the first messaging libraries used for clusters. However, these protocols are typically implemented using operating system services. To send a message, a user application constructs the message in user memory, and then makes an operating system request to copy the message into a system buffer. An interrupt is required for this operating system intervention before the message can be sent out by network hardware. When a message is received by network hardware, the network copies the message to system memory, and an interrupt is used to copy the message to user memory, and to notify the receiving process that the message has arrived. This operating system overhead is a significant portion of the total time to send a message. As networks became faster during the 1990s, the overhead of operating system services became significantly larger than the actual hardware transmission time for messages. The goal of the low-latency messaging systems that were developed during the 1990s was to avoid operating system intervention while at the same time providing user-level messaging services across high-speed networks.

Low-overhead messaging systems developed during the 1990s include Active Messages (von Eicken 1993), Fast Messages (Culler et al. 1996), the VMMC (Virtual Memory-Mapped Communication) system (Blumrich et al. 1995), and U-net (Basu, Welsh, and von Eicken. 1997), among others. By 1997, research on low-latency protocols had progressed sufficiently for a standards process to be initiated, and the Virtual Interface Architecture design document was formulated and published as a standard low-latency networking architecture in less than a year.

Active Messages, which was later extended to Generic Active Messages (GAM), is a low-latency communication messaging library for the Berkeley NOW system. Short

messages in Active Messages are based on the concept of a request-reply protocol. The sending user-level application constructs a message in user memory. To transfer the data, the receiving process allocates a receive buffer, also in user memory on the receiving side, and sends a request to the sender. The sender replies by copying the message from the user buffer on the sending side directly to the network. Network hardware transfers the message to the receiver, and then the message is transferred from the network to the receive buffer in user memory. This process requires that memory on both the sending and receiving sides be pinned to an address in physical memory. However, once the memory buffers are established, no operating system intervention is required for a message to be sent. This protocol is also called a “zero-copy” protocol, since no copies from user memory to kernel memory are used. In GAM, a copy sometimes occurs on the receiving side so that buffers can be reused more efficiently, in which case the protocol is referred to as a “one-copy” protocol. Fast Messages is a protocol similar to Active Messages, but extends Active Messages by imposing stronger guarantees on the underlying communication. In particular, Fast Messages guarantees that all messages arrive reliably and in order, even if the underlying network hardware delivers messages out of order.

The VMMC system, later extended to VMMC-2, is the enabling low-latency protocol for the Princeton Scalable High-Performance Really Inexpensive Multi-Processor (SHRIMP) system. One goal of VMMC is to view messaging as reads and writes into the user-level virtual memory system. VMMC works by mapping a page of user virtual memory to physical memory, and in addition makes a correspondence between pages on the sending and receiving sides. VMMC also uses specially designed hardware that allows the network interface to snoop writes to memory on the local host and have these writes automatically updated on remote host memory. Various optimizations of these writes have been developed that help to minimize the total number of writes, network traffic, and overall application performance. VMMC is an example of a class of systems known as distributed shared-memory systems. In these systems memory is physically distributed among the nodes in a system, but processes in an application may view “shared” locations as identical and perform reads and writes to the shared locations.

The U-net network interface architecture strongly influenced the design of the VIA. In addition to providing zero-copy messaging when possible, U-net, and VIA add the concept of a virtual network interface for each connection in a user application. Just as an application has a virtual memory address space that is mapped to real physical memory on demand, each communication end point of the application is viewed as a virtual network interface mapped to a real set of network buffers and queues on demand. The advantage of this architecture is that once the mapping is defined, each active interface has direct access to the network without operating system intervention. The result is that communication can occur with very low latency.

The VIA is a standard that combines many of the best features of various academic projects, and will strongly influence the evolution of cluster computing. Although VIA can be used directly for application programming, it

is considered by many systems designers to be at too low a level for application programming. With VIA, the application must be responsible for allocating some portion of physical memory and using it effectively. It is expected that most operating system and middleware vendors will provide an interface to VIA that is suitable for application programming. Generally, the interface to VIA that is suitable for application programming comes in the form of a message-passing interface for scientific or parallel programming.

APPLICATION DEVELOPMENT

To develop accurate and efficient high-performance applications, it is essential to have some form of easy-to-use parallel debugger and performance profiling tools. Most vendors of cluster systems provide some form of debugger and performance analyzer for their platform. Ideally, these tools should be able to work in a heterogeneous environment. Thus, it is possible to develop and debug a parallel application on an inexpensive cluster, and then perform production runs on a dedicated cluster-based HPC platform.

Parallel Programming Support

The programming paradigm for cluster computing falls primarily into two categories: message passing and distributed shared memory. Although distributed shared memory is claimed by some to be an easier programming paradigm, as the programmer has a global view of all the memory in the cluster, early standardization efforts, have instead focused on message-passing systems. Some of the most popular languages that were developed during the late 1980s and early 1990s included Express, NX, PVM (Parallel Virtual Machine, 1990), P4, and Chimp. In reaction to the wide variety of nonstandard message-passing systems around this time, the MPI Forum (1993) was formed as a consortium of about 60 people from universities, government laboratories, and industry in 1992. MPI version 1.0 was approved as a de jure standard interface for message-passing parallel applications in May 1994. The Forum continued to meet, and in April 1997, the MPI-2 standard was published. MPI-2 includes additional support for dynamic process management, one-sided communication, and parallel I/O. Many implementations of MPI-1 have been developed. Some implementations, such as MPICH, are freely available. Others are commercial products optimized for a particular manufacturer's system, such as the Sun HPC MPI. Generally, each MPI implementation is built over faster and less functional low-level interfaces, such as Active Message, BSD Sockets, or the SGI/Cray SHMEM interface. The PVM system is a research-and-development project of the Oak Ridge National Laboratory and the University of Tennessee at Knoxville.

Since much of early cluster computing was performed by application programmers who had previously programmed on supercomputers, early efforts focused on developing message-passing libraries for application programs comparable to those found on supercomputers. Early message-passing libraries all had support for at least

the creation of processes, as well as sending and receiving messages between the processes.

To write parallel programs for a cluster, scientific programmers generally write applications in a high-level language such as C or FORTRAN, and include, by linking, a message-passing library. The program is written as source code, compiled, and linked, and the programmer starts the program by executing a script file that runs the application on a set of named computers. Usually the computers are identified by IP addresses or names. A background demon manages the creation of remote processes. Generally, applications are based on the SPMD (single program multiple data) programming model. Each process is a copy of the same executable code, and program behavior depends on the identifier of the process. Processes exchange data by sending and receiving messages.

The first version of the MPI standard does not specify how standard input and output are to be implemented. Typically, an application programmer initiates a parallel application from a console. If a process in the application prints to standard output, then a background demon directs the output to this console. Output from different processes will be interleaved on the console and arrive in a nondeterministic order. This problem can be overcome if the application programmer specifies that only one process write to standard output. Standard input to an application is usually performed only by root (the process running on the console), or is retrieved from the local disk of the computer that the process is executing.

The first release of the MPI standard specifies support for collective operations, and nonblocking sends and receives. Collective operations in MPI are those that have either more than one sender or more than one receiver. MPI-1 supports broadcast, scatter (of array elements from root to other processes), gather (of array elements from other processes to root), reduce (gather with a combining operation, such as the summation of array elements from other processes to root), and variations of these, such as all to all, all reduce, and all gather. MPI also implements a barrier synchronization, which allows all processes to come to a common point in a program before proceeding. MPI collective calls provide a more convenient interface for the application programmer and are often implemented using special, efficient, algorithms.

MPI-1 specifies standards for nonblocking sends and receives. These are usually a two-step operation in which the process first initiates the send (receive) call, and then uses a second call to ensure that the buffer is safe to be reused or that the data have arrived. These nonblocking calls can be used by programmers to facilitate the overlapping of communication and computation.

The second release of the MPI standard, MPI-2 specifies additional standards for one-way communications, similar to the writes to shared, distributed memory locations that were developed in VMMC and other academic systems. MPI-2 also specifies a standard way to create MPI processes, support for heterogeneous platforms, extended collective operations, I/O operations, and multi-threading on individual computers.

Debuggers

There are a limited number of parallel debuggers available for a cross-platform, heterogeneous, development environment. For this reason an effort was begun in 1996 to define a cross-platform parallel debugging standard that specified the features and interface users wanted. The High Performance Debugging Forum (HPDF) was formed as a Parallel Tools Consortium (PTools) project (1993). The HPDF members include vendors, academics and government researchers, as well as HPC users. The forum meets at regular intervals, and its efforts have culminated in the HPD version 1 (High Performance Debugging Forum 2000) specification. This standard defines the functionality, semantics, and syntax for a command-line parallel debugger. The development of cross-platform parallel debuggers is an area of active research. Ideally, a parallel debugger should be capable of at least:

- Managing multiple processes and threads within a process
- Displaying each process in its own user window
- Displaying source code, stack trace, and frame for one or more processes
- Diving into objects, subroutines, and functions
- Setting both source-level and machine-level breakpoints
- Sharing breakpoints between groups of processes
- Defining watch and evaluation points
- Displaying arrays and array slices
- The manipulation of code variables and constants

Performance Analysis Tools

Performance analysis tools exist to help programmers understand the run-time characteristics of their applications. In particular, tools help to analyze and locate parts of an application that exhibit poor performance and produce program bottlenecks. Such tools are useful for understanding the behavior of normal sequential applications and can be enormously helpful when trying to analyze the performance characteristics of parallel applications, which are typically more complex.

To create performance information, most tools produce performance data during program execution and then provide a tool to do a postmortem analysis and display of the performance information. Some tools do both steps in an integrated manner, and a few tools have the capability for run-time analysis, either in addition to or instead of postmortem analysis. Most performance monitoring tools consist of some or all of the following components:

- A means of inserting instrumentation calls to the performance monitoring routines into the user's application
- A run-time performance library that consists of a set of monitoring routines that measure and record various aspects of program performance
- A set of tools that process and display the performance data

In summary, a tool for postmortem performance analysis works by:

- Adding instrumentation calls into the source code
- Compiling and linking the application with a performance-analysis run-time library
- Running the application to generate a trace file
- Processing and viewing the trace file

A particular issue with performance-monitoring tools is the intrusiveness of the tracing calls and their impact on the application's performance. It is important that instrumentation does not affect the performance characteristics of the application and thus provide a false view of its performance behavior. A lesser, but still important, secondary issue is the format of the trace file. The file format is important for two reasons. First, it must contain detailed and useful execution information but not be huge, and second, it should conform to some "standard" format so that it is possible to use various GUI interfaces to visualize the performance data. The development of standard, non-intrusive performance tools is an area of active research.

ADVANCED TOPICS

Emerging Trends

A number of hardware trends are having an impact on cluster computing. Two of these trends are in the design and manufacture of microprocessors. One basic advance is the reduction in the size of features, which has allowed circuits to either become faster or consume less power. A second basic advance is the growth in the size of the die that can be manufactured. These factors mean that each year the average number of transistors on a chip is growing by about 40% and the clock frequency is increasing by about 30%.

Memory components are experiencing similar growth, but there is an increasing divergence between the capacity and the speed of memory. For example, the capacity of memory components increased by a factor of more than 1000 between 1990 and 2005, but speed has only doubled. Consequently, the increase in memory speed is not matching that of microprocessors. Therefore, access to data in memory is becoming a significant bottleneck. One method of overcoming this bottleneck is to configure the DRAM in banks and transfer data from these banks in parallel. In addition, multi-level memory hierarchies organized as caches make memory access more effective, but their design is complicated. This access bottleneck also applies to disk access, and consequently, to the virtual memory system of a computer.

A number of high-performance networks have been used successfully as cluster interconnects, including Fast Ethernet, Gigabit Ethernet, SCI, Myrinet, Giganet, InfiniBand, Fibre Channel, and others. Since no network has emerged as a clear winner, competition is high, and this will continue to impact price and performance. For some applications, particularly those for which the amount of data exceeds the size of physical memory, it is possible

to use messaging across a high-performance network to obtain data faster than data can be obtained from a processor's own memory. These high-performance networks make cluster computing an attractive architectural alternative to the memory bottleneck of a single processor system.

Clusters dedicated to high-performance applications will continue to evolve as new and more powerful computers and network technologies become available in the marketplace. It is likely that individual cluster nodes will be composed of multiple processors. Currently multi-core-processors PCs and workstations are becoming common. Software that allows SMP nodes to be used efficiently and effectively by parallel applications will be further developed or enhanced and added to the operating system kernel in the near future. It is likely that there will be widespread use of 10-Gigabit Ethernet, as this technology will provide a low-risk solution for moving from standard or switched Ethernet. The price for using this technology will be higher communication latencies. In situations in which it is necessary for an application to attain very low latencies, network technologies that bypass the operating system kernel, thus avoiding the need for expensive system calls, will be used. This can be achieved using intelligent network interface cards or, alternatively, using on-chip network interfaces such as those on Digital Equipment Corporation's DEC Alpha 21364.

Field programmable gate array (FPGA) is another possibility to speed up computation and communication. For instance, some of the message-passing protocol can be implemented on the card, which improves acknowledgment latency and offloads some work from the processors. Furthermore, the FPGA can be configured to improve computational performance and not interact directly with network.

The two most popular operating systems for clusters are Linux and Windows. Linux has become popular because it is freely available as well as because of its increasing stability and its performance, which is superior to that of Windows. There are currently more than seven million Linux users worldwide, and its future development is being supported by many companies, such as IBM and Compaq. Linux is also available for SMP systems that have two or more processors per node. Windows XP has a large installed user base, and is gradually replacing the huge existing Windows 95/98 user base. A new version of Windows, Windows Compute Cluster Server 2003, implements the MPI Interface (MS-MPI), which is fully compatible with the reference MPICH2. Furthermore, the integration with Active Directory enables role-based security for administration and users, and the use of Microsoft Management Console provides a familiar administrative and scheduling interface, which can support the use of standard communication technologies. The ability to provide a rich set of development tools and utilities as well as the provision of robust and reliable services will determine the choice of the operating system used on future clusters. UNIX-based operating systems are likely to be most popular, but the steady improvement and acceptance of Windows will mean that it will not be far behind.

Next-Generation Cluster Computing

As computer networks become cheaper and faster, a new computing paradigm has emerged, known as the Grid (Foster, Kesselman, and Tuecke 2001). The Grid is a large system of computer-based resources that performs tasks and provides users with a point of access, commonly based on a Web interface, to widely distributed resources.

One view of the Grid is as a single computational resource. Resource management software accepts jobs submitted by users and schedules them for execution on appropriate systems in the Grid, based on site policies. Users can submit thousands of jobs at a time without being concerned about where they run. The Grid may scale from single systems to supercomputer-class computer farms that use thousands of processors. Depending on the type of applications, the interconnection between the Grid resources can be performed using dedicated high-speed networks or the Internet. By providing scalable, secure, high-performance mechanisms for discovering and negotiating access to remote resources, the Grid promises to make it possible for scientific collaborators to share resources on an unprecedented scale and for geographically distributed groups to work together in ways that were previously impossible. Several examples of new applications that benefit from using Grid technologies are:

1. A coupling of advanced scientific instrumentation or desktop computers with remote supercomputers
2. Collaborative design of complex systems via high-bandwidth access to shared resources
3. Ultra-large virtual supercomputers constructed to solve problems too large to fit on any single computer
4. Rapid, large-scale parametric studies, e.g. Monte-Carlo simulations, in which a single program is run many times in order to explore a multidimensional parameter space

The Grid technologies are currently under intensive development. Major Grid projects include the Open Science Grid (2004), TeraGrid (2000), iVDGL (International Virtual Data Grid Laboratory 2001), and the EGEE (Enabling Grid for E-science 2006) project. Grid tools are available for developers today. The Globus Toolkit (2002) represents one such example and includes a set of services and software libraries to support grids and its applications.

CONCLUSION

Our need for computational resources in all fields of science, engineering, and commerce far outstrips our ability to fulfill these needs. The use of COTS-based clusters is perhaps one of most promising means by which we can bridge the gap between our needs and the available resources.

A major hurdle for cluster computing is that of education. Because of the parallel and distributed nature of clusters, computer science and other students must be trained in programming techniques that do not ordinarily arise on single-CPU or client/server-based systems; writing correct and efficient programs is more difficult

in a cluster environment. Similarly, the architectural issues that arise in building clusters are more complex. The standard undergraduate curriculums in computer science and computer engineering only partially cover these topics. These curriculums need to be expanded to meet the needs of industry as cluster computing becomes more common.

The use of a COTS-based cluster has a number of advantages, including:

- An unmatched price/performance ratio as compared with dedicated parallel supercomputers
- The ability to incrementally grow a system and thus take advantage of yearly funding patterns as well as being able to incorporate the latest technologies
- The provision of a multi-purpose system: one that is, for example, used for secretarial purposes during the day and as a commodity supercomputer at night

These and other factors will continue to fuel the evolution of cluster computing.

GLOSSARY

AMD: Advanced Micro Devices.

ATM: Asynchronous transfer mode, a network and protocol for wide area network.

Bandwidth: The amount of data that can be transmitted in a fixed amount of time, usually expressed in bits per second (bps) or bytes per second.

Beowulf-CLASS System: Commodity cluster using personal computers to achieve excellent cost performance, which was initially developed by the Beowulf project, led by Donald Becker and Thomas Sterling, at the NASA Goddard Space Flight Center.

COTS: Commodity Off-The-Shelf.

DIMM: Dual in-line memory module, a small circuit board that has a 64-bit path to memory chips.

Ethernet: The first widely used and truly ubiquitous local area network operating at 10 Mbps.

Fast Ethernet: A cost-effective local area network based on the original Ethernet protocol, providing 100 Mbps.

FTP: File transfer protocol.

Gbps: 1 billion bits per second data transfer rate of bandwidth.

Gigabit Ethernet: A LAN that is the successor of Fast Ethernet, providing a peak bandwidth of 1 Gbps.

GNU: A project that promotes open source and free software tools.

InfiniBand: An input/output architecture for the transmission of data between processors and I/O devices.

LAN: Local area networks used to connect local sites.

Latency: The amount of time it takes a network packet to travel from source to destination.

Local bus: A data bus that connects directly, or almost directly, to the microprocessor.

Mbps: 1 million bits per second data transfer rate or bandwidth.

Message Passing: An approach to parallelism based on communicating data between processes running on separate computers.

MPI: Message passing interface, a community derived logical standard for the transfer of program messages between separate concurrent processes.

NIC: Network interface controller, a hardware component that enables the computer to connect to a network, usually designed for a particular type of network, protocol, and media.

PC: Personal computer.

PCI: Peripheral component interconnect, a local bus standard for PCs and workstation to support I/O controllers, including NICs.

PVM: Parallel virtual machine, a library of functions supporting an advanced message-passing semantics.

RAM: Random access memory.

SAN: System area network, a network optimized for use as a dedicated communication medium within a commodity cluster.

SCI: Scalable coherent interconnect.

SIMM: Single in-line memory module, a small circuit board that has a 32-bit path to memory chips.

SMP: Symmetric multi-processing, a multi-processing architecture in which multiple CPUs, residing in one cabinet, share the same memory.

SPMD: Single program multiple data, a programming model designed for multiprocessors system, in which parallel programs run the same subroutine but operate on different data.

TCP: Transmission control protocol.

VIA: Virtual interface architecture.

WAN: Wide area networks used to connect distant sites.

INTRODUCTION

Since nearly the beginning of the modern era of digital electronic computers, there has been interest in ganging together multiple processors to achieve higher computational capacities than a single prevailing processor could provide. Although there is a wide range of system and algorithmic challenges to overcome to effectively parallelize an application, it has long been recognized that a high-speed communications network that can enable processors to efficiently exchange data and control information is critical. Ideally, such a network should offer seamless transparency between the primary memory systems of the processors, or more directly, their speed (bandwidth) and latency (temporal delay) should be commensurate with the high-speed memory system. The ultimate goal for efficient communications would be for a parallel processor machine to stay continuously busy performing useful work, without waiting for data or control to transfer between processors. This has given way to one basic measure of efficiency (N_{eff}) for such machines (Fox 1984):

$$N_{\text{eff}} = T_{\text{pe}} / (T_{\text{pe}} + T_{\text{com}}) \times 100,$$

where T_{pe} is the time that the processor element spends doing useful work and T_{com} is the time that the processor must wait for communications, control, and other system functions to complete before it can resume.

From this simple relationship, one can assess the overhead for an application algorithm on a given multiprocessor architecture. For example, for applications in which infrequent communication occurs between long stretches of computation, the so-called embarrassingly parallel applications, a much lower performance network can be used with virtually no degradation in overall performance, and at a lower cost as well. Conversely,

for fine-grained applications, in which many messages must be exchanged after a given computation, higher-bandwidth, lower-latency networks are required. From this application- or algorithm-centric point, system communication needs can be generalized as flops per byte. The higher the number, the more infrequent the communications, generally implying that a lower-performance network can be used.

With gigahertz-class processors, many gigabytes per second (GB/s) with latencies of a few nanoseconds (ns) would be needed. Furthermore, other fundamental limits of physics begin to enter the picture, especially with regard to latency. At some point, the speed of light represents a fundamental limit that cannot be overcome because of the finite distances between components for even the densest of packaging schemes. For this reason plus a host of others, in recent years much interest has focused on novel computer architectural methods for mitigating these problems—e.g., keeping processors busy while waiting for other system functions to complete, whether they be communications, the operating system, or other system functions (see van der Steen, 2006, for an overview of modern supercomputer architecture and system elements). In many cases, new processor and system designs are required to fully realize these latency-hiding methods, and will continue to be the subject of research.

Although it would certainly be interesting to review all of the parallel computers and their interconnect systems that have been developed since the Illiac IV in the 1960s, but without losing too much context, one could cut to the chase and begin with the Beowulf commodity PC cluster developed in 1994 by Thomas Sterling (Sterling et al. 1999; Sterling 2001), then at Goddard Space Flight Center (Ridge et al. 1997). Although commodity microprocessors had been incorporated into parallel clusters almost ten years earlier (Seitz 1985), this is the first

instance in which commodity motherboards and network components combined with open source software (mostly Linux) had also been used to maximize the performance/price ratio. There were functionally similar concepts being developed elsewhere at about the same time, such as the Berkeley Network of Workstations (NOW) or Apollo Workstation clusters, which used single-vendor-computer platforms with proprietary operating systems and networks. Today, Beowulf clusters have been commercialized or packaged by many vendors, both from well-known names as well as start-ups. Most, in fact, use the same basic components, but add value in terms of integration, support, and management tools. Today, more than 70% of the machines listed on the world's top 500 supercomputers (see www.top500.org) are clusters, and if one includes proprietary networks as well, the figure approaches 100%. Approximately 50% of the top 500 supercomputers use Gigabit Ethernet (Kaplan 2001) as the primary interconnect, followed by approximately 11% for Myrinet and 7% for Infiniband. More details of the current state of the art of cluster computer network technology can be found in *Cluster Computing Fundamentals* and additional references (Apon 2001; Bode 2004).

This chapter will first review the salient performance metrics by which cluster computer networks can be compared, and then briefly review the general classes of the networks that have emerged in recent years, both from an architectural viewpoint as well as from a protocols perspective. Next, a few case studies will be examined among the more common networks in use today. And finally, some future directions that show promise to meet the needs of the next generation of high-performance computer systems and architectures will be explored.

INTERCONNECTION NETWORKS

In contemporary multiprocessor high-performance computing systems (HPCs), the processor-memory interconnect is often the single most constraining bottleneck in overall system performance (Dally and Towles 2004). This problem originates from the limitations of electronic hardware to provide sufficient bandwidth and low latency over the physical size of the computing system. Alternative interconnection technologies have been proposed as a means of eliminating the severity of this bottleneck. Perhaps the most promising of these alternative technologies are those that leverage optical signal transmission on networks composed of photonic devices and fiberoptic components (Special Issue on Optical Interconnections 2004).

Whereas electronic transmission is limited by signal degradation and losses that rise with frequency, optical transmission degradation is functionally independent of frequency and suffers only minimal degradation over long distances. This well-known advantage of optical transmission has led to the wide use of fiber optics in nearly all long distance telecommunication systems (Agrawal 2002). HPC systems are typically very large and highly distributed, with diameters spanning tens to hundreds of meters, so the capability of covering such distances with high bandwidth and low latency while consuming minimal

power represent some of the significant advantages for optical interconnects. For transmitting high data rates over long distances, optical fiber is far better suited than copper. Furthermore, because of the multiple-wavelength nature of light, conventional optical fiber is capable of transmitting more multiple-terabits per second (Tbps) in a wavelength-parallel or wavelength-division multiplexed (WDM) manner (Agrawal 2002), surpassing electronics by many orders of magnitude. A third benefit of optical signal transmission is its immunity to electromagnetic cross talk and interference; this advantage is particularly useful in high-noise digital computing systems. Last, and perhaps most critical, is the clear power-dissipation advantage of optical interconnects. This key advantage of optical interconnection networks is based on a property of the photonic medium, known as bit-rate transparency. Unlike electronic routers, which switch with every bit of the transmitted data while dissipating dynamic power that scales with the bit rate, photonic switches switch on and off at the message rate, and their energy dissipation does not depend on the bit rate. This property facilitates the transmission of very-high-bandwidth messages while avoiding the increasingly high power costs typically associated with performing such communication with equivalent electronic networks (Miller 2000).

Although it is all but certain that future generations of multiprocessor HPC systems will eventually leverage these optical technologies, photonic and optoelectronic devices are unfortunately not yet as mature and developed as comparable electronic components. Although some photonic interconnects are used in the backplanes of commercial HPC systems, advanced optical interconnection networks are still primarily an area of research. The performance of these devices is not yet as stable and robust as comparable electronic components, and the current pricing can pose a significant deterrence to large-scale commercialization. Although the importance of these weaknesses cannot be overlooked, ongoing research and development are rapidly improving optical and photonic technologies, and many experts are optimistic about their progress. Part of this optimism stems from the recent progress in integrated photonic devices fabrication in Complementary Metal Oxide Semiconductor (CMOS) compatible platforms [this is discussed further in Case Study 5].

In order to fully use the immense bandwidth and other benefits of optical signal transmission, network architectures must be designed in a way that specifically addresses the unique properties of optical technologies. That is, conventional canonical topologies that have been very successfully implemented with electronic components cannot simply be mapped into the photonic implementations. The single biggest architectural difference between electronic and optical media is that practical optical buffers are not available and are physically challenging to implement; RAM structures are nearly impossible to implement for optically transmitted signals. Also, it can be very challenging to execute significant data processing entirely within the optical domain (Blumenthal 2001; Luijten et al. 2005; Shacham, Small, Liboiron-Ladouceur, and Bergman 2005; Small, Kato, and Bergman 2005).

Fully assimilating the unique characteristics of optical technologies into interconnection network design presents novel challenges. Traditional network design principles, which are based on electronic implementations, rarely can be applied to the new technology. Instead, new paradigms for interconnect design must be adopted to accommodate the optical signal transmission. These paradigms should consider the multiple-wavelength nature of light, the lack of optical buffering and processing technologies, and the problems and costs inherent in converting signals between optical and electronic domains. A few ideas have been developed to address the future needs of optical telecommunications networks, particularly ones based on the schemes of optical packet switching (OPS) and optical burst switching (OBS), and some of these principles are beneficial to the case of photonic HPC interconnects as well (Blumenthal et al., 1992; Qiao and Yoo 1999; Hemenway et al. 2004; Barker et al. 2005; Shacham, Small, Liboiron-Ladouceur and Bergman 2005). However, the design space remains largely unexplored and is an active area of research. The challenge is to find the optimally cost-effective combination of electronics and optics to achieve the best system level performance.

Here we present principles for photonic interconnection network design that address the aforementioned challenges. The discussion is extended into possible future developments of optical interconnection network architectures intended for monolithic integration, with applications to interchip and intrachip interconnects.

The implementation of low-latency, high-capacity switching interconnection systems has benefits to numerous applications within modern data processing and communications. Leveraging the ubiquity of conventional fiber-optic components allows for a realistic network implementation that is modular, scalable, and robust. By allowing high-volume multiple-wavelength optical packets to traverse a network with minimal processing and routing logic, a complete system can be constructed for experimentation and characterization. By establishing the attractiveness of contemporary fiber-optic technology and its general flexibility, the strategies and merits of the presented architectural paradigm are elucidated.

OPTICAL INTERCONNECTION NETWORKS: TECHNOLOGIES, ARCHITECTURES, AND SYSTEMS

Design Considerations

The photonic interconnection architectural paradigm presented here is intended to have extraordinarily high capacity while exhibiting very low routing latencies. The targeted data rates are on the order of hundreds of gigabits/sec (Gbps) from each network terminal. This surpasses the current electrical interconnection technologies by almost a full two orders of magnitude (see www.top500.org; Flich et al. 2002; Petrini et al. 2002; Hurwitz and Feng 2004; Liu et al. 2005). Latencies are expected to be less than 1 μ s for typical packet traffic configurations, and the interconnection networks are intended to be scalable beyond 10,000 input and output terminals. These performance specifications are in line with the

needs for next-generation high-performance computing applications. In order for the system to have a reasonable uptime, the system error rate must be better than about 10^{-22} or about three errors per year for a 10,000-terminal 100-Gbps network, which implies that physical errors must certainly stay below 10^{-12} per channel, while using forward error correction (FEC) coding and other appropriate error-correcting techniques.

Using current fiber-optic communication technologies, bit rates of 10 Gbps (i.e., OC-192 or STM-64) per wavelength channel are typical. Because it is often convenient to have packet capacities on the order of 1000 bits over ten or more parallel wavelengths, packet lengths are typically tens of nanoseconds in duration, with packet rates near 100 MHz. The carrier frequencies of the channels within the optically encoded packets are set by the International Telecommunications Union (ITU) to span a range of 190.1 THz to 196.1 THz, or 1528.8 nm to 1577.0 nm, over what is called the “C-band” of the electromagnetic spectrum. The wavelengths are generally spaced by 100 GHz (0.8 nm) by the wavelength division multiplexing (WDM) standard; the dense WDM standard specifies 50-GHz (0.4-nm) spacing. These wavelengths can be transmitted over commercially available single-mode optical fiber with attenuations of just 0.3 dB/km. The chromatic dispersion (i.e., the rate at which longer wavelengths travel faster than shorter ones) is typically 18 ps/nm/km or less (Agrawal 2002).

To summarize the metrics and scales to be used in the discussion of interconnection networks: 10-channel data rates can exceed 100 Gbps with packet rates of 10 MHz or more, latencies are generally measured in hundreds of nanoseconds, and distance scales on tens of meters. The information is encoded optically according to the C-band WDM specifications, which contains sixty-one channels over the 48-nm span. The devices used often benefit from the technological advances encouraged by long-haul fiber optics while avoiding many of their physical shortcomings. The resulting networks are room-sized and suitable for numerous applications within high-performance data processing and communications.

Enabling Photonic Technologies

The advantages of fiber optic technologies have long been clear to network designers. Electronic signals suffer from numerous wave transmission difficulties, including reflections, Ohmic loading, and electromagnetic interference, all of which result in limitations to transmission distance and bandwidth and lead to excessive power consumption (Miller 2000). Optical waves can be transmitted with high data rates over monumental distances with very little power consumption. For these reasons alone, network architectures that incorporate photonic and fiberoptic elements could potentially offer significant benefits. Network designers generally relegate fiber optics to a transmission medium; however, interest has gradually emerged in performing switching and routing functions with optical signals instead of electrical ones. Although this sort of processing is obviously very well suited for contemporary microelectronic technology, the costs of converting signals between the electrical and

optical domains can be quite prohibitive in terms of financial expense, latency, and power. Using photonic devices for switching functions within an interconnection network is therefore worth considering.

Beginning in the 1980s, when the data rates for fiber-optic communications were significantly slower than they are today, a few ideas about the structure of a scalable photonic switching network began to emerge. Many of these architectures incorporate a device that was relatively new to that decade, the semiconductor optical amplifier (SOA), also called the semiconductor laser amplifier. The SOA is a device capable of amplifying optical signals over a wide optical bandwidth with significantly less latency and less power than the popular erbium-doped fiber amplifier (EDFA) and Raman amplifier. Furthermore, SOAs require a relatively small amount of electrical power to turn on, and the necessary current can be provided relatively quickly. This results in a switchable wideband photonic device that is controlled electrically with low latency and minimal rise time (Blumenthal et al. 1992; Fortenberry, Cai, and Tucker 1994; Krishnamoorthy et al. 1999; Wonglumsom et al. 1999; Meagher et al. 2000; Armstrong, Andonovic, and Kelly 2004; Lin et al. 2006).

The first presentation of an SOA-based optical packet switching (OPS) node occurred in the late 1980s (Evankow and Thompson 1988), and during the early 1990s the idea gained minor attention and experienced small conceptual advances (Blumenthal et al. 1992; Fortenberry et al. 1994). This design is a simple Y-junction with two SOAs, one on each branch, and most of the designs require the SOAs to provide gain to compensate for the losses of the Y-junction and perhaps other passive optical taps and splitters in the former part of the node (Figure 1). The control and routing mechanism in these designs is either entirely electrical or based on a conventional time-division multiplexed (TDM) header.

Because this simplistic approach does not benefit from the multiple-wavelength nature of optical signals, other ideas that capitalize on wavelength parallelism began to ascend to the forefront of OPS research. These switching network designs often use the parallel transmission of multiple wavelengths as a mechanism for contention resolution or for destination addressing. Beginning in the mid-1990s, numerous unique switching node designs and architectures (e.g., Krishnamoorthy et al. 1999; Wonglumsom et al. 1999; Meagher et al. 2000) for OPS were developed and presented in the literature, many of which are based on a standard library of photonic

devices, including SOAs, wavelength-tunable lasers, optical filters, arrayed waveguides (AWGs), and lithium niobate (LiNbO_3) switches. Summaries and comparisons of these architectures have also been published (Papadimitriou, Papazoglou, and Pomportsis 2003). Unfortunately, a shortcoming of many of these architectures is the degree of complexity required of the optical components for addressing ("label processing") at other logical functionality.

Some of the designs mentioned above use different switching methods as well. In many of the AWG-based designs, the network is better classified as a circuit switch; that is, a designated pathway between an input terminal and an output terminal is established, and communications occur on that pathway. This approach differs markedly from packet switching, in which discrete "flits" of information are routed independently, not based on the state of the underlying switching fabric. These AWG-based approaches generally rely on the wavelength of the packet itself as the means of encoding the destination address; although wavelength bands can also be used, this wavelength addressing scheme makes it impossible for terminals to service packets that are simultaneously encoded over the entire wavelength span, minimizing network bandwidth.

Although many of these architectures are meant to be implemented as routers within telecommunications networks, and therefore may have to adhere to established protocols, the packet structures are fundamentally optically encoded forms of a conventional electronic sequential header-payload packet. This structure fails to capitalize on the unique modulation schemes available to the optical domain, most especially multiple-wavelength encoding. Even though the wavelength dimension can be leveraged for contention resolution and for destination address quite effectively, one of the principal concerns for high-performance interconnection networks to be used in the applications mentioned above is high payload capacity. Clearly, multiple-wavelength data encoding over the C-band has the potential to yield the largest net transmission bandwidth.

Specialized devices that produce multiple-wavelength optical signals based on electrical inputs and the reverse are currently produced commercially, with results reported for as much as 10 wavelengths $\times$ 40 Gbps (see www.infinera.com). These transmitters and receivers represent the interface between the electrical signals that originate from the cluster nodes and the optical signals that are transmitted or perhaps even switched throughout an optical network. By leveraging the high-density integration

Figure 1: Schematic of simple wideband single-packet (left) and nonblocking (right) 2×2 switching nodes based on photonic switching elements (e.g., SOAs)

available to monolithic designs, these transmitters and receivers can easily accommodate ten high-speed electrical signals and the necessary optical/electronic (O/E) or electronic/optical (E/O) conversions. One of the companies that produces these integrated multiple-wavelength transmission devices successfully is Infinera, in Sunnyvale, California (see www.infinera.com). Their technology is based on a III-V semiconductor substrate that can support lasers, high-speed modulators, and high-speed photodetectors.

Another interesting company is Luxtera, in Carlsbad, California (see www.luxtera.com), which has taken a different approach. They used a silicon substrate as a workbench for a host of photonic devices, including modulators, which can more easily be integrated with conventional CMOS electronic devices. This allows for electrical signal processing and management to be contained on the same chip as the photonic devices. Although silicon is less amenable to optical devices in general, this “CMOS Photonics™” paradigm, as they call it, certainly has great potential in making the transition between the electrical and optical domains more seamless and flexible.

Regardless of the technology, then, the multiple-wavelength packet structure is a defining distinction between historical architectural designs and the paradigm presented here. Another distinction is the simplicity of the control mechanism that has been used in an effort to reduce routing latency.

Architecture Design

Optical networks should capitalize on the advantages of photonic technology while acknowledging its current shortcomings. The single most important advantage of optical signal encoding is the enormous bandwidth it can support, both because of the high-modulation bandwidth available to a signal channel (i.e., carrier frequency or carrier wavelength) and because of the large number of wavelength channels that can be transmitted simultaneously. With a total of 6 THz of bandwidth available for optical transmission over the C-band, efficient coding techniques can certainly support transmission capacities of more than 1 Tbps (Agrawal, 2002).

However, the strong disadvantage of optical information systems is the inability to perform arithmetic operations with agility and robustness near that of CMOS and other electrical logic families. Indeed attempts have been made to implement simple logical functions with photonic and fiber-optic technologies, but by and large, these are not yet stable nor integratable enough for arithmetic computations of even minor complexity (Agrawal 2002). Similar to this essential absence of optical logic devices is the difficulty of implementing RAM and buffers with photonic and fiberoptic technologies. These two shortcomings are important to keep in mind in the design of optical interconnection network architectures.

To summarize, an ideal design for such a network should capitalize on the gargantuan bandwidth available to fiberoptic technologies while minimizing the burden of computation and buffering on the photonic network components. Indeed, it is even beneficial to distinguish

between the path and devices through which the high-bandwidth payload travels and the path and components that carry the routing information and execute the routing decision. That is, an ideal optical interconnection network design leaves the transmission capacity to the optical domain and relies on better-suited electronic technologies for routing and decision mechanisms.

In addition, in order to address general networking concerns such as scalability and modularity, multiple-stage distributed topologies are often used in interconnection networks, independent of the transmission medium (Dally and Towles 2004). For a large number of network input and output terminals, it is important that the number of switching nodes required to implement a complete topology scales efficiently. Further, it can be beneficial for a given implementation to comprise nearly identical switching nodes that need only to be configured with their position within the interconnection network, as is common for various multiple-stage topologies. For a large number of input and output terminals, it is also important for the control and routing mechanism to scale efficiently. Whereas centralized arbitration algorithms can become computationally burdensome for large numbers of network terminals at fast packet-injection rates, a distributed control scheme that delegates routing to each individual switching node can simplify the routing mechanism (Dally and Towles 2004).

In order to further simplify routing and architectural organization, packet switching is a method by which multiple input terminals can freely communicate with multiple output terminals. Designated transmission lines between every input and every output is clearly a wasteful use of resources. Moreover, because the optical switching nodes would likely subtend only hundreds of bit periods of latency, the model of circuit switching may not be fitting either. As an example, consider packets with 10 Gbps (OC-192) payloads: one hundred of these bits requires 10 ns, or 2.0 m in standard single-mode optical fiber (e.g., SMF-28). Given the current degree of integration of contemporary fiber-optic components, it is unlikely for a complete network to fit within just 2 m. Besides, there may be well more than a 2-m displacement between client terminals in the applications mentioned above. Therefore, a packet-switching perspective is perhaps most appropriate for this kind of network design. A packet-switching network based on distributed switching nodes in a multiple-stage topological configuration may therefore define an ideal architectural design space.

These topological specifications, along with the aforementioned delegation of capacity and functionality, yield an interesting switching-node design. The basic SOA-based Y-junction structure, which is almost two decades old, is still the fundamental structure of the payload optical pathways. In the design of an optical switch element, ultra-high bandwidth packets are achieved by using multiple wavelengths for packet payload encoding. Because the SOA switching elements are capable of amplifying signals over almost the full span of the C-band, the potential packet payload capacity is maximized. A whole two-dimensional matrix of payload data can be encoded in both the time dimension and the wavelength dimension by leveraging this approach.

Additional wavelengths can be designated for the packet header, which contains the necessary routing information. In order to simplify detection of the header bits and to facilitate the routing, each of the header bits may be encoded on a distinct wavelength. Thus, an n -bit header requires an additional n wavelengths more than those designated for the packet payload. However, having only one bit of information to decode on each wavelength for the entire duration of the packet dramatically simplifies header detection. One function that is simpler with photonic devices than with electronic devices is channel demultiplexing. Because of the wavelength nature of light, isolating one of these header wavelengths simply requires an optical filter. For a two-way switching node, two header bits are sufficient to establish all possible switching states. The control plane of the switching nodes is therefore driven by two simple optical filters and two low-speed optical receivers. After the optically encoded header bits have been decoded into electrical signals, all switching-node routing logic can use electronic logic devices with relative simplicity. Then the routing decision is executed by enabling one of the two SOA switching elements (Small, Shacham, and Bergman 2005). The routing for each node is entirely contained within that node, resulting in a distributed switching architecture.

Moreover, the packets should traverse the node structure in a manner that is almost perfectly transparent: optical power is preserved and very little signal distortion is introduced. In the implementations, great effort is taken to ensure that the signal exiting the switching node is almost identical to the one that entered. The losses introduced by the Y-junction and other passive optical components are exactly matched by the gain introduced by the SOA. The SOA is also operated in a regime in which very few nonlinearities occur in order to best preserve signal integrity. This structure allows for many switching nodes to be cascaded in a modular way that is almost independent of the path through the network and the number of nodes traversed. The packets fly through the system without significant degradation, traveling from one node to the next.

In order to best serve this switching-node design, the network must follow a bufferless topology. Clearly, the simple switching-node design that has been developed above lacks buffering and store-and-forward capabilities. The optical packets traverse the Y-junction at exactly the speed of light in fiber, and there is no means of halting the packet flow or even slowing it down. These restrictions are easily serviced by the architectural implementation of deflection routing or, similarly, hot-potato routing (Dally and Towles 2004).

In summary, optical interconnection network topologies, along with the switching-node designs and optical packet formats, are designed to leverage the unique benefits of fiberoptic and photonic technologies while avoiding their shortcomings. Buffering and packet storage are not required; this is avoided by deflection routing. Logical computations executed in optical media are not required; instead, digital electronic devices compute the switching-node routing decision. Moreover, the packet payload is encoded optically as a high-bandwidth multiple-wavelength structure that transparently propagates the network as a

unit, staying in the optical domain throughout the entire network. Only the low-bandwidth headers are converted to the electronic domain, allowing packets to fly through the network uninhibited, with time-of-flight latencies approaching speed-of-light limitations. Using a water-flow (fire-hose) metaphor, the high-bandwidth optical packet can flow through the switching fabric, with the switching nodes as nearly transparent valves that direct the flow of this unstoppable deluge; the headers serve only to temporarily set the state of the branches. The benefits of fiber optics are complemented, not hindered, by electronics in a cooperative arrangement that maximizes the throughput of the interconnection network and minimizes transmission latencies.

Metrics

The performance of networks can be quantified by a few key metrics. Latency describes the duration required for a packet to enter the input interface (including possible input buffering) and then exit completely from the output interface; network latency includes processing times as well as the traversal “time of flight” or routing latency. The quantity of packets or information that are successfully routed by the network in a single time slot (or specified unit of time) is the throughput or bandwidth; an accurate measure of this is the bisectional bandwidth, which is defined in more detail below. Also important is the acceptance rate—of the offered load, or total quantity of packets that are presented to the network in a particular timeslot, generally some packets are rejected and must wait to be routed by the network, or be routed at a later time. When the offered load becomes so high that the acceptance rate begins to diminish, the network is said to be saturated.

Although latency, throughput, and acceptance rate are the most important measures, a few other network properties can be of interest to network designers as well. These include the more abstract attributes such as scalability, expandability, and simplicity, as well as reliability or robustness, recoverability, and reparability. And for network architectures to actually be implemented, designers must also consider financial cost or price and electrical power consumption. A complete view of network design must be concerned with both the performance metrics and these engineering and implementation considerations.

The bisectional bandwidth measures the total throughput flowing from one half of the network to the other. That is, if we imagine cutting the network geometrically in half, bisecting it between input terminals and output terminals, the throughput that traverses this boundary represents a much more meaningful measure of the aggregate network bandwidth; this is the bisectional bandwidth. Because, in general, packets cross this boundary only once, packets are counted correctly, and because the boundary crosses the entire network, the bisectional bandwidth accounts for any localized congestion or irregularities.

Even before a network reaches saturation, there are instances when not all packets are accepted into the network for routing and delivery. That is, not all of the packets offered into the network—the offered load—are immediately accepted into the network for routing.

Thus, the acceptance rate quantifies the fraction of the packet traffic that actually enters the network for routing compared with the offered load. Packets that are rejected may be buffered in one of the stages discussed above; in rare cases, packets may simply be discarded, although this option can have grave repercussions for overall system performance. All of the processing of the network interface modules counts against the latency of the network, although the routing latency can be used to describe the amount of time required between the network interface modules, discounting buffering and processing.

The key metrics for next-generation high-bandwidth interconnection networks, such as those described in this chapter, are throughput (bandwidth), latency, and acceptance rate. It is important to consider how design decisions affect each of these. The case studies provided below represent different approaches to reaching an optimal region of this design space.

CASE STUDIES

In this section, we examine a few of the emerging very-high-speed interconnection networks capable of supporting at least 100 Gbps per port, and petabits/sec to exabits/sec bisection bandwidth. These are meant to be representative of some of the key research work of the field. Most of this is experimental, but it is indicative of future trends in the field and the impending challenges. The proposed 100-Gbps Ethernet standard, which channelizes 10-Gbps Ethernet over as many WDM channels or stripes, is probably the nearest term of these, but relying on traditional electronic switching, does not offer a very elegant switching mechanism and can be expensive to implement in large-scale architectures. Other more specific optical solutions that are described include ShuffleNet, Data Vortex, and OSMOSIS. Finally, as very-large-scale integrations tip past the billion-transistor-per-chip level, many systems will rely on large arrays of multicore processor chips in which the on-chip internal bus must act as an extension of the larger global interconnection network. In fact, with clock speeds in the multiple-gigahertz range, on-chip latencies will pose similar problems that chip-to-chip network designers faced a decade earlier. Early on-chip network concepts that address these challenges include SPINet as well as possible successors to several on-chip buses for the current vintage of multicore processor chips. Common traits of these networks are low latency that can support fine-grained messages efficiently, very high speeds per port (>100 Gbps), dual E/O implementation approaches that enhance scalability to very large systems of thousands to millions of processor elements.

Case Study 1: 100-Gigabit Ethernet

By far the most popular and least expensive network interconnection technology for clusters, especially low-cost commodity clusters, is Ethernet. The original concept for Ethernet was invented (and patented) by Bob Metcalfe at Xerox PARC in 1973, but it was not commercialized until the late 1970s, when Xerox, Intel, and Digital Equipment Corporation (DEC) joined forces to propose a standard

(called DIX) that specified the carrier sense multiple access/collision detection (CSMA/CD) protocol at 10 Mbps over a coax. In 1983, the first IEEE 802.3 standard appeared that was basically backward-compatible with the DIX standard. Over the next two decades, the standard was enhanced numerous times to support other forms of media and increased speed. Most notable, the modern-day 100 Mb/s (or Fast) 100BaseT standard (802.3u) appeared in 1995, followed by 1000BaseT standard (802.3z), and 10-Gigabit (802.3ae) standard by 2002. And there is advance planning underway for 100-Gigabit Ethernet, although that is not likely to appear any earlier than 2010 (more on this below).

One of the real advantages of Ethernet is that high-volume commodity pricing has made network interface controller (NIC) adapters so cheap that 10/100/1000 Mbit/s host adapters are placed on nearly every processor motherboard built today. With a price point that is typically under 1% of the motherboard cost, some motherboards actually incorporate multiple interfaces for applications such as servers, peripheral input/output (I/O) farms, routers, network attached storage, and to no surprise, cluster computer compute nodes.

With such versatility and widespread adoption, Ethernets have found several niches in Beowulf PC clusters. First, in very-low-cost systems, they of course serve as the primary interconnection network for interprocessor communications. In higher-end clusters, where an ultra-high-performance network such as Infiniband (Shanley 2002; Liu 2005), Myrinet (Flich 2002), or QsNet (Petrini 2002) is used for the primary interprocessor communications, Ethernet is often used to support secondary functions, such as system administration, control, external I/O, maintenance, and of course, backup to the primary network.

Over the span of almost 30 years, Ethernet has progressed from the original 10 Mbps standard of the late 1970s, through 100 Mbps, 1 Gbps, and now 10 Gbps standards. Although Gigabit Ethernet is backward-compatible with Fast (100 Mbps) Ethernet, a number of changes were made to the physical layer, and a large part of the data exchange protocols to improve performance and support high bandwidth media. Data rates in the 400-to-700-Mbps range are typical with TCP/IP using jumbo frames (9000 bytes), and slightly better results are possible with user datagram protocol (UDP). Unfortunately, the latency remains high in the few-hundred-microsecond range, primarily because of the TCP/IP overhead. The cost of Gigabit Ethernet switch equipment is non-negligible in figuring the overall system cost, but is expected to continue to fall as the commercial market volumes increase.

Although the standard for 10-Gigabit Ethernet has been in place since 2002, its market penetration has been gradual because of the high cost and low volumes, much of this because the earlier Gigabit Ethernet still satisfies much of the commercial and consumer need.

Early trials of a possible 100-Gigabit Ethernet standard have already been successfully attempted (GRID Today 2006) by aggregating 10×10 -Gbps Ethernet channels over as many WDM channels of an optical fiber. Channel-bonding schemes are introduced to guarantee that frames

arrive in order at the destination. A prototype of this system was developed and demonstrated that relies on a single-chip 100-Gigabit Ethernet network interface that implements a lane-alignment and packet-resequencing scheme to bond ten parallel 10-Gbps channels into one logical flow while maintaining packet ordering at the receiver. This eliminates the need for high-speed serial/parallel multiplexers and clock recovery methods and the resulting performance issues (such as increased logic complexity and signal delay) that can arise with the use of the existing link aggregation techniques for combining multiple data channels. Services that combine multiple wavelengths to offer a single service are referred to as “super-lambda services.” To date though, such a system would be cost-effective only as a wide area network. However, with appropriate refinements and increased volumes of the switch and NIC chip technology and optoelectronics, it is possible that such a system could become cost-effective as a system interconnect. However, based on the somewhat slower adoption of 10-Gigabit Ethernet, this might evolve as a somewhat slower rate over the next decade.

Case Study 2: Optical ShuffleNet

All OPS networks, both long haul and computer system interconnects, have been investigated since the late 1980s, when the National Science Foundation (NSF) and Defense Advanced Research Projects Agency (DARPA) began some investments in this area. Although most of the attention at the time was focused on long haul and wide area network systems, there were a few early investigations that focused on interconnects for parallel computer systems that were just beginning to become a dominant force in the high-performance-computing industry. One of these was ShuffleNet (Hluchyj and Karol 1991; Feehrer, Sauer, and Ramfelt 1994), in which optical packets are launched into a fiber-optic omega network of 2×2 optical switches (Figure 2). The method uses deflection routing to detect packet address header information on

the fly, and then correctly throw 2×2 LiNbO₃ switches to the correct position for the optical packet to reach its next point in the network. The data payload of the packet never needs to be decoded electronically, thus reducing latency of the switch point and more importantly, overall system complexity. Also, in principle, the bandwidth of the packets can be much higher than normal since electronic regeneration is not required at each 2×2 switch. If two packets arrive at the 2×2 switch at the same time and both packets are vying for the same outbound port, then one packet is intentionally deflected on a nonoptimal outbound port, which may cause the packet to take a longer path, and incur more latency, on its way to its destination. This elegant form of congestion arbitration uses the network itself as a memory buffer to store packets on the fly when the same resources are being contented for.

The ShuffleNet scheme can be implemented using TDM or WDM or both technologies. One disadvantage of the scheme is the topology, in which the number of links and 2×2 switches required scales as $N \log N$ as the number of processors (or network ports) increases. More efficient use of network fabric while sacrificing very little in terms of network bisection bandwidth and network saturation characteristics can be found in the Data Vortex, which is discussed in the next section. Another significant disadvantage is that deflected packets must traverse the entire network again and again until they reach the correct output port, which can potentially lead to severe congestion.

Case Study 3: Data Vortex

The Data Vortex topology was designed specifically for implementation as an OPS network and developed primarily at Columbia University beginning in 2002. The Data Vortex architecture requires no routing buffers and can be constructed from simple single-packet 2×2 switching nodes. The multiple-stage construction of the architecture allows for a node-element building block, which must be modified only slightly depending on its

Figure 2: Illustration of an 8×8 ShuffleNet (omega) topology, composed of nonblocking 2×2 switching nodes

location with the topology. Because of this high degree of modularity, the implementation of a complete network is not an unsurpassable prospect, and it has been demonstrated, yielding a fully implemented terabit-capacity switch (Shacham, Small, Liboiron-Ladouceur, and Bergman 2005; Hawkins and Small 2007).

This project also developed a new architectural paradigm, which was used in designing the Data Vortex network. First, in order to unleash the bandwidth potential of optical transmission, multiple-wavelength (or wavelength-parallel) encoding is used for the packet payload. Each wavelength can be modulated at a high data rate (10 Gbps or higher) itself, and multiple wavelengths (sixteen or more) are transmitted in parallel throughout the network. Second, the multiple-stage (or multistage) interconnection network (MIN) contains many switching nodes between the input and output terminals, as in the ShuffleNet, and each of these switching nodes is made to be “transparent.” This means that the switching nodes allow the optical information to pass through with nearly no physical change to the encoded information; power levels are preserved (or amplified following attenuations), and no signal processing is done. Thus, switching nodes can be cascaded in any sequence and at almost any length (Small, Shacham, and Bergman 2005). Third, header information is transmitted with 1 bit per wavelength to simplify decoding and minimize the latency of the routing logic. These three architectural features are independent of the topology and can be used for a variety of optical network architectures. The focus of this case study, however, is on the specifics of the Data Vortex architecture.

The Data Vortex architecture is designed for scalability to large port counts with potentially thousands of communicating terminals and thus uses a distributed routing scheme rather than central arbitration (Hawkins

et al. 2007). In order to best accommodate scalability and address the problem of the absence of reliable dynamic photonic buffers, the conventional butterfly network topology is modified to contain integrated deflection routing pathways. The primary consideration in the organization of the architecture is enabling the optical packets to approach speed-of-light time-of-flight latencies. The switching nodes are therefore designed to be as simple as possible and to contain as little routing logic as possible, so that the packets do not have to be delayed while routing decisions are made. These design considerations naturally result in a very modular architecture, and one that is scalable and self-similar in such a way that a small-system implementation can help predict the performance of larger networks.

The Data Vortex topology integrates internalized buffering with banyan-style bitwise routing to result in a bufferless network, ideal for implementation with fiber-optic components. The structure can be visualized as a set of concentric cylinders or routing stages that are cyclic subgroups that allow for deflections without loss of routing progress. Moreover, the hierarchical multiple-stage structure is easily scaled to larger network sizes while uniformly maintaining fundamental architectural concepts (Hawkins et al. 2007).

This implementation of the Data Vortex architecture is meant as a demonstration of its viability and as a testbed for system analyses. The smallest-size Data Vortex topology of interest (i.e., one that demonstrates features common to larger systems) is a 12×12 network, which contains 3 cylinders of height 4 and 3 angles, viz. $(C, H, A) = (3, 4, 3)$. These parameters indicate that a 4×4 banyan structure is augmented with an internal deflection buffering dimension of 3. The entire system is comprised of thirty-six single-packet 2×2 switching nodes (Figure 3).

Figure 3: Three-dimensional illustration of the Data Vortex topology

The switching nodes are interconnected using a set of ingress fibers, which connect nodes of the same height in adjacent cylinders, and deflection fibers, which connect nodes of different heights within the same cylinder. The ingress fibers are of the same length throughout the entire system, as must be the deflection fibers. The deflection fibers' height-crossing patterns direct packets through different height levels at each hop to enable banyan routing (e.g., butterfly, omega) to a desired height, and assist in balancing the load throughout the system, mitigating local congestion (Hawkins et al. 2007; Hawkins and Small 2007; Hawkins and Wills 2006).

Because a complete deflection routing scheme is implemented, acceptance rates of nearly 100% can easily be achieved for the Data Vortex architecture (Yang and Bergman 2002). Although this requires a small degree of overprovisioning, the result is well worth it: the implemented Data Vortex system is in practice able to accept more than 160 Gbps (16 wavelengths at 10 Gbps) of traffic to each of its twelve input ports at every clock cycle. Because wideband SOAs are used as the only switching element, the network can potentially support packets composed of wavelengths that span the entire C-band. Not only has successful routing been demonstrated on the implemented system, but various physical measurements and characterizations have been performed as well (Small, Liboiron-Ladouceur, et al. 2005; Small et al. 2006; Small, Shacham, Athikulwongse, Hawkins, Bergman, and Wills 2004), which attest to the robustness and scalability of the architecture.

Case Study 4: OSMOSIS

In the OSMOSIS project, a hybrid electro-optical approach using electronics for buffering and scheduling, and optics for transmission and switching, is adopted. This system uses components and technologies currently available, and demonstrates that this hybrid approach easily allows for the implementation of a high-performance system (Hemenway et al. 2004). This project was a collaborative effort between IBM Research and Corning in the early 2000s.

For the OSMOSIS network, an SOA-based 64×64 crossbar switching fabric has been constructed and a high-speed scheduling algorithm has been developed to

maximize its utilization (Figure 4). SOAs are used as the cross-points in the switching fabric, and 40-Gbps peak bandwidth per port is demonstrated. Internal paths are wavelength-multiplexed in the switching fabric to reduce the number of SOAs and the total cost. However, the wavelength-based routing used in the second stage of the crossbar restricts packets to single-wavelength transmission. High-throughput figures must therefore be the result of high modulation rates.

The simple and predictable structure of the optical pathways results in packets being routed with a fixed and known latency, unlike the Data Vortex architecture, in which deflections can result in variable packet latencies. In order to successfully manage the 64×64 crossbar, a central arbiter must schedule each pathway assignment between the requested input and output ports. By leveraging an electronic application-specific integrated circuit (ASIC) to execute the routing computations, the high-bandwidth packet transmission of the optical domain can be made very simple. This hybrid approach is what allows the OSMOSIS switch to deliver such high-bandwidth figures with very high packet acceptance and minimal propagation latency.

Although being the closest to actual implementation and possible commercialization, having shown a running prototype, the OSMOSIS architecture may not be the choice sought for very-large-scale systems. A scheduled crossbar requires additional communication lines, limits scalability, and is often accompanied by a notable queuing delay. In the suggested fat-tree architecture, packets can experience this delay several times, resulting in a latency penalty.

Measurements and performance evaluations have been performed on the implemented prototype system (Hemenway et al. 2004). Because the structure of the optical pathways is so simple, the network provides a large degree of physical flexibility. However, the central arbitration unit can become a system bottleneck if the routing algorithm becomes saturated. There has, therefore, been a significant effort to optimize the crossbar-arbitration algorithm and minimize overhead. The OSMOSIS architecture represents a truly unique hybridized approach to optical interconnection, leaving the high-bandwidth transmission to the optical domain, and using high-speed electronics for the routing and decision making.

Figure 4: Schematic of the OSMOSIS (64×64 broadcast-and-select) architecture. (Source: Hemenway, 2004)

Case Study 5: OPSNET

Recent collaborations between a research group at Cambridge University and Intel Research has resulted in a router architecture that is similar to both the OSMOSIS and Data Vortex projects. As with those architectures, SOAs are used as the primary switching element. The OPSNET network topology of this router is a simple arbitrated crossbar structure, although it can accommodate multiple-wavelength (wavelength-striped) packets as well (Figure 5; Lin et al. 2006).

In a more advanced implementation, two crossbars are cascaded in order to deliver higher port counts. In addition to providing the routing functionality, field programmable gate array (FPGA) controllers are also programmed to equalize packet power and optimize the physical-layer properties of the routed packets.

The first-stage switch fabric is configured as a broadcast and select 4×4 -switch-using fused fiber couplers and commercially sourced low-polarization sensitivity semiconductor optical amplifiers. No power equalization is performed in the first-stage switch, with power levels being deliberately mismatched at the input to the second-stage switch. The arbiter is implemented in a fairly sophisticated FPGA and is configured to route the WDM packets cyclically from the three hosts to the input of the second-stage fabric.

The second switch fabric is similarly equipped to implement the required paths of a 4×4 broadcast and select switch. Unused paths are terminated with attenuators as shown by the open boxes. The amplifiers are instead illustrated by filled boxes in Figure 5. Optical isolators are placed after each SOA. The second-stage SOA switch routes the packets from the first stage to the test port and implements the digital controller for power equalization. The input power is tapped with a 10:90 coupler, filtered, sampled, and digitized with 12-bit resolution to update the look-up table in the controller.

The control plane is implemented with partitioned FPGA. Low-line-rate 1-Gbps O-band transceivers are set to ensure time-slot synchronization between the hosts and the central arbiter. The control and data channels are

transmitted on the same fiber using low-loss broadband-wavelength multiplexers. To avoid delaying the packets, the power-equalization settings for each time slot are defined ahead of payload arrival at the switch. Control information specifying the implemented paths between hosts is therefore transmitted ahead of the packets to avoid the need for delay at the optical layer. To ensure scalability, component-specific data are abstracted from the higher networking layers using a multilayered control plane.

This prototype network demonstrates that electronics can be used for physical-layer control as well as routing within high-bandwidth optical interconnection networks. This is another example of an architecture in which the optical medium and photonic devices are used as the means of conveying extremely-high-bandwidth packets, and conventional high-speed electronics are used for setting up the photonic pathways and managing the optical packets.

Case Study 6: Chip-to-Chip SPINet

The main impediment to the construction of photonic interconnection networks lies in the high cost and large footprints associated with using discrete optical elements such as lasers, modulators, switches, and passive optics. Photonic integration, the fabrication of circuits implementing many photonic functions in a single package, is promising to eliminate these final barriers (Williams 2006). When photonic integration is harnessed to construct interconnection networks, however, buffering becomes very difficult. The optical packet occupies a fixed length of a waveguiding medium, which is the product of the speed of light in the medium and the duration of the packet. A typical 100-ns packet will occupy 20 m of silica fiber or 6 m of a semiconductor waveguide. Consequently, buffering optical packets within a photonic integrated circuit (PIC) is not currently practical, and interconnection networks based on photonic integration should be truly bufferless, using other means of contention resolution.

The SPINet (Scalable Photonic Integrated Network) architecture is designed to be implemented using photonic integration technology (Shacham et al., A scalable,

Figure 5: Schematic of the OPSNET architecture, with two cascaded 4×4 stages. © OSA 2007, *J. Opt. Netw.*

self-routed, 2005). Based on an indirect MIN topology, SPINet exploits WDM to simplify the network design and to provide very high bandwidths. SPINet does not use buffering, and resolves contention by dropping contending messages. A novel physical layer acknowledgment protocol provides immediate feedback notifying the terminals whether their messages are accepted and facilitates retransmissions when necessary, in a manner resembling traditional multiple-access media. In this section we describe SPINet's concepts, its design parameters, and its performance under various scenarios.

A SPINet network is a transparent optical MIN, comprised of 2×2 SOA-based bufferless photonic switching nodes. Topologically, it is very similar to the ShuffleNet described above, although the physical scale of a SPINet network is much smaller, and some of the particulars of contention resolution differ. The network can be of any indirect binary topology, in which 2×2 switching nodes are used. In the original implementation an Omega topology was chosen because of its simple stage-interconnection pattern. An $N_T \times N_T$ Omega network consists of $N_S = \log_2 N_T$ identical stages. Each stage consists of a perfect-shuffle interconnection followed by $N_T / 2$ switching elements, as shown in Figure 6, where $N_T = 8$. The switching nodes are nonblocking, so data from both input ports may be received and routed simultaneously.

The entire network is envisioned to be integrated on a PIC, and its terminals are physically located on the computing nodes of the HPC system and are connected to the PIC by optical fibers. The terminals are assumed to be synchronized, the network is slotted and synchronous, and messages have a fixed duration. The minimal slot duration is determined by the round-trip propagation time of the optical signal from the terminals to the PIC. A slot time of 100 ns can, therefore, accommodate a nearly 20-m propagation path and a distance of 10 m between the terminals and the PIC.

Figure 6: An 8×8 omega network schematic of a SPINet design with an end-to-end lightpath

At the beginning of each slot, any terminal may start transmitting a message, without a prior request or grant. The messages propagate in the fibers to the input modules on the PIC and are transparently forwarded to the switching nodes of the first stage. At every routing stage when the leading edges of the messages are received from one or both input ports, a routing decision is made and the messages continue to propagate to their requested output ports. In the case of output-port contention in a switching node, one of the contending messages is dropped. The choice of which message to drop can be random, alternating, or priority-based. Since the propagation delay through every stage is identical, all the leading edges of the transmitted messages reach all the nodes of each stage at the same time.

Using the ultra-low-latency propagation through the PIC, SPINet eliminates the need for central scheduling using the distributed computing power of the switching nodes to produce an I/O match at every slot. This process of implicit arbitration enables scalability to large port counts without burdening a central arbiter with computing complex maximal matches. Because blocking topologies are used, to reduce hardware complexity, the network's utilization is lower than that of a traditional maximum-matched nonblocking network (e.g., switching fabrics of high-performance Internet router). In subsequent sections, techniques that exploit the properties of integrated photonics to increase utilization by adding a small number of stages are investigated.

The packet structure used for the SPINet network is almost identical to the one described for the Data Vortex architecture, above. Multiple-wavelength packets can be used, since the switching elements have a very wide optical bandwidth. Certain wavelengths can be designated for use by the payload and modulated at high data rates, whereas other wavelengths are reserved for header and routing information.

The wavelength parallel structure also facilitates a low-cost solution for E/O conversion: the replacement of prohibitively expensive high-speed serial modulators and receivers with a set of lower-speed devices to attain the same bandwidth. These devices can be, for example, low-cost directly modulated 2.5-Gbps vertical-cavity surface-emitting lasers (VCSELs) or even on-chip silicon modulators/receivers. The achievable low-cost bandwidth and the network's inherent wide switching band and bit-rate transparency suggest a bandwidth-time trading: for a given required peak bandwidth, an $\times S$ speedup is used in the wavelength domain, while the packet rate (the load offered to the network) is reduced by a $1/S$ factor. For example, for a port designed to provide a peak bandwidth of 40 Gbps, eight wavelengths are modulated at 10 Gbps each, and a new packet is generated once every two slots, on average. This $\times 2$ speedup lowers the load offered to the network, thus leading to reduced queuing latency.

Case Study 7: Multicore Networks-on-Chip

A major design paradigm shift is currently impacting high-performance microprocessors as critical technologies are simultaneously converging on fundamental performance limits. Accelerated local processing frequencies

have clearly reached a point of diminishing returns: further increases in speed lead to tighter bounds on the logic coherently accessed on-chip, and the associated power dissipation is exacerbated in an exponential fashion. Evidence of this trend is unmistakable, as practically every commercial manufacturer of high-performance processors is currently introducing products based on multicore architectures: AMD's Opteron, Intel's Montecito, Sun's Niagara, and IBM's Cell and Power5. Clearly, within the next few years, performance gains will come from increases in the number of processor cores per chip, leading to the emergence of a key bottleneck: the global intrachip communications infrastructure. Perhaps the most daunting challenge to future systems is to realize the enormous bandwidth capacities and stringent latency requirements when interconnecting a large number of processing cores in a power-efficient fashion.

Low-latency, high-data-rate, on-chip interconnection networks have therefore become a key to relieving one of the main bottlenecks to chip-level multiprocessing (CMP) system performance. Significant research activity has focused on intrachip global communication using packet-switched micronetworks. These so-called networks-on-chip (NoCs) are made of carefully engineered links and represent a shared medium that is highly scalable and can provide enough bandwidth to replace many traditional bus-based and/or point-to-point links. However, with a fixed upper limit to the total chip-power dissipation, and the communications infrastructure emerging as a major power consumer, performance-per-watt is becoming the most critical design metric for the scaling of NoCs and CMPs. It is not clear how electronic NoCs will continue to satisfy future communication bandwidths and latency requirements within the power dissipation budget.

Photonic interconnection networks offer a potentially disruptive technology solution because of their fundamentally low power dissipation compared with equivalent electronic interconnects that remain independent of capacity while providing ultra-high throughputs and minimal-access latencies. One of the main drivers for considering photonic NoCs is the expected reduction in power expended on intrachip communications. The key power saving rises from the fact that once a photonic path is established, the data are transmitted end to end without the need for repeating, regeneration, or buffering. In electronic NoCs, on the other hand, messages are buffered, regenerated, and then transmitted on the inter-router links several times en route to their destination.

The building blocks are nanoscale PICs that use optical microcavities, particularly those based on ring resonator structures shaped from photonic waveguides, which can easily be fabricated on conventional silicon and silicon-on-insulator (SOI) substrates. High-speed optical modulators, capable of performing switching operations, have been realized using the free carrier plasma dispersion effect in these ring resonator structures or in Mach-Zehnder geometries. SiGe-based photodetectors and optical receivers are the final component necessary for making an entire self-contained PIC, and a few designs for these have been suggested recently (Special Issue on Nanoscale Integrated Photonics, 2007).

In fact, IBM and Intel, as well as other companies, have launched serious research efforts in this area, and have been developing a host of the optoelectronic and photonic devices that would be required to assemble a complete NoC. These foundries are interested in enhancing the performance of their already planned multicore CPU architectures. The most recent advances of each of these corporations are typically announced publicly and with fanfare (see www.intel.com/go/sp and www.research.ibm.com/photonics).

The proposed novel architecture of the hybrid photonic-electronic on-chip network is based on a two-layer structure: (1) a photonic interconnection network, comprised of silicon broadband photonic switches interconnected by waveguides, is used to transmit high-bandwidth messages; and (2) an electronic control network, mimicking the topology of the photonic network, in which each electronic router controls a photonic switch. The main advantage of this approach relies on a property of the photonic medium, known as bit-rate transparency. Unlike electronic routers, which switch with every bit of the transmitted data while dissipating dynamic power scaling with the bit rate, photonic switches switch on and off at the message rate, and their energy dissipation does not depend on the bit rate. This property facilitates the transmission of very-high-bandwidth messages while avoiding the power cost that is typically associated with them in traditional electronic networks.

The architecture leveraged for these nanoscale PICs relies on a similar hybrid approach to network design as is leveraged for the macroscale case studies given above. High-bandwidth optical packets are routed through photonic devices entirely within the optical domain; only the routing and arbitration is controlled by high-speed electronics.

COMPARISON OF BASIC APPROACHES

All of the optics-based case studies discussed above are united by one fundamental design principle: optics and photonics are used for transmitting the payload information across the network, and conventional electronics are used as the means of controlling the network flow. It is universally recognized that the potential bandwidth available for optical transmission vastly surpasses that of any contemporary electronic system, and will be necessary after 100-Gigabit Ethernet no longer meets the bandwidth demands of cluster computing systems. Somehow leveraging the 6 THz of bandwidth available within the C-band of the optical spectrum is a feature common to the architectures discussed above. Although devices for all-optical network control are currently being researched, these design approaches recognize that the technology is still far from being robust and able to be commercialized. On the other hand, these networks allow for payloads to be sent across the whole network in the optical domain from beginning to end; it is not necessary to convert between optics and electronics once signals enter the network.

It seems that a dominant trend for the next generation of cluster interconnection networks is toward lightwave systems, which rely on conventional electronics for routing management and arbitration. This design approach is

clever in that it allows the two technological media (viz. electronics and optics) to do what each is best at: nothing to date can beat the sheer computational flexibility and simplicity of CMOS electronics, and optical signal encoding is the ideal high-bandwidth low-power method of transmitting information.

Although the architectures discussed above share this common design principle, they differ in many significant ways as well. Many of the approaches, such as ShuffleNet, OSMOSIS, OPSNET, and SPINet, topologically resemble more familiar networks, although the details of their implementation are specific to optics. In one case, the Data Vortex, an entirely new topological scheme was developed to fit the underlying optical transmission medium. Some of these network architectures, such as OSMOSIS and OPSNET, rely on centralized arbiters for managing packet routing and network flow control; whereas the ShuffleNet, Data Vortex, SPINet architectures are composed of discrete switching nodes that execute routing decisions individually, resulting in a distributed network control mechanism.

For all network topologies, optoelectronic devices are required for switching the optical signals based on electronic inputs, serving as the interface between the optical signal plane and the control plane. Many of the architectures described above rely on SOAs because they can deliver gain while maintaining very short propagation latencies and fast switching times. The ShuffleNet, mostly developed before SOAs were commercially available, instead leverages LiNbO₃ switches, which introduce signal loss. In either case, the discrete optoelectronic switching devices play a central role in the network: hundreds or thousands of them must be assembled and connected for the completed system. The benefit of monolithically integrated systems, such as SPINet or NoCs, is that the switching devices can be formed on the substrate in a way that is more elegant than the bulk-scale devices.

Despite some of the apparent differences between the projects discussed above, they all seek to optimize and improve upon already existing technology and maximize network throughput and transmission bandwidth. By alleviating the key interconnect bottleneck in cluster and multiprocessor interconnection networks, the ultimate computing power of these systems can truly be unleashed.

PROSPECTS FOR REALIZATION (BARRIERS, TECHNOLOGY, OR ECONOMIC)

As discussed above, a key element of the proposed next-generation optical network architectures is the optoelectronic switching elements. Although they have improved vastly, in both performance and price, over the past decade, they still have a way to go before being competitive with gigahertz-scale microelectronics. But like any emerging technology, improvements will come rapidly once there is appreciable economic incentive (Miller 2000). As the interconnect bottleneck in HPC systems becomes more and more detrimental to system performance, these next-generation technologies will become more attractive. The good news is that the technology for these solutions

already exists, and designs have already been developed. In this way, cluster interconnect architectures are ahead of their time.

Monolithically integrated technologies are making significant advances as well. Demonstrations of fully functional components and subsystems have illustrated the feasibility of PICs for interconnection networks (Special Issue on Nanoscale Integrated Photonics, 2007). These on-chip interconnects have the potential to service multicore platforms and improve the performance of CPU chips themselves.

All of these next-generation architectures are exciting prospects. Because of the forthcoming severity of the supercomputer interconnect problem, these systems have valuable contributions to make to the advance of supercomputing power. By making the most of advancing technologies, these technologies show great promise in being part of the next generation of cluster computing.

CONCLUSION AND AREAS TO WATCH

What are the emerging trends? Moore's law is showing signs of slowing, at least in terms of processor clock speed. However, the Silicon Industry Association (SIA) roadmap is showing continued decrease in feature size through 2015 (see www.public.itrs.net), meaning that chip density will continue to increase. In turn, this will enable larger multicore processor chips, larger memory systems, higher levels of integration (fewer chips per motherboard), and wider data buses and greater precision logic (64-bit is hitting stride). All of these will apply back pressure for network speeds to increase, at least to the compute node (where multiple processors may reside). As Intel and AMD are now investigating moving the graphics engine onto the processor chip, doing the same for network host adaptor(s) would make sense to some, but many packaging challenges remain. But there are other downsides, in that network architecture and speed advances would have to be now in lockstep with processor advances—probably not very desirable. In terms of the network components, 100-Gigabit Ethernet is beginning to be explored by standards groups, and if it reaches convergence, products likely would not appear any sooner than 2010. Undoubtedly, other vendors will also explore product feasibility in this range. However, increased packaging density combined with higher speed and larger parallel data paths may possibly forge new directions in networking. For example, three-dimensional chip packaging may make it attractive to reexplore two-dimensional optical interconnects, which when combined with WDM, would enable tens of terabits to be coupled into one chip stack.

As speeds climb past 100 Gbps per port and to very wide data paths, other all-optic network concepts may become more viable, with speeds approaching ~1 terabits/sec (Tbps) per port. Examples include the ShuffleNet (Fehrer, Sauer, and Ramfelt 1994), which scales to very large systems using 2×2 optical switch building blocks, and the Data Vortex (Shacham, Small, Liboiron-Ladouceur, and Bergman 2005), which uses WDM for increased parallelism. One attribute of many of these networks is

that the optical media topology and the routing protocol are designed as one unified system, minimizing or eliminating the need for fast-switching electronics at each network-switching node. Although many of these concepts have been proven in the laboratory, none (as yet) have reached commercial viability. But this could change in the years ahead, and certainly if and when it happens, it would represent a major paradigm shift.

GLOSSARY

Beowulf-Class System: Commodity cluster using personal computers to achieve excellent price and performance initially developed by the Beowulf Project at Goddard Space Flight Center.

CMP: Chip Level Multi-Processing

COTS: Commodity off-the-shelf

CRC: Cyclic redundancy checksum

CSMA/CD: Carrier sense multiple access/collision detection

DARPA: Defense Advanced Research Projects Agency

E/O: Electronic/optical

FEC: Forward Error Correction

GB: Gigabyte

GB/s: Gigabytes/sec

Gbps: Gigabits/sec

HPCS: High-performance computing systems

I/O: Input/output

IP: Internet protocol

ITU: International Telecommunications Union

MB: Megabyte

Mbps: Megabits/sec

Myricom: Vendor, distributor, and developer of the Myrinet network for commodity clusters

NIC: Network interface controller

NOW: Network of Workstations

ns: Nanosecond

NSF: National Science Foundation

O/E: Optical/electronic

OPS: Optical packet switching

PC: Personal computer

PCI: Peripheral component interface

PCI-X: PCI Extended

PIC: Photonic integrated circuit

Quadrics: Commercial vendor of networking hardware and software for QsNet

SIA: Silicon Industry Association

SOA: Semiconductor optical amplifier

TCP: Transmission control protocol

Tbps: Terabits/sec

μs: Microsecond

VIA: Virtual interface architecture

WDM: Wavelength division multiplex

INTRODUCTION

The growing popularity of the Internet and the availability of powerful computers and high-speed networks as low-cost commodity components are changing the way we do computing. These technological developments have led to the possibility of using networks of computers as a single, unified computing resource, known as “cluster computing” (Buyya 1999; Pfister 1998). Clusters appear in various forms: high-performance clusters, high-availability clusters, dedicated clusters, nondedicated clusters, and so on. In addition, computer scientists in the mid-1990s, inspired by the electrical power grid’s pervasiveness and reliability, began exploring the design and development of a new infrastructure, computational power grids, for sharing computational resources such as clusters distributed across different organizations (Foster and Kesselman 2003).

In the business world, cluster architecture-based large-scale computing systems, called “data centers,” offering high-performance and high-availability hosting services are widely used. The reliable and low-cost availability of data center services has encouraged many businesses to outsource their computing needs; thus heralding a new utility computing model.

Utility computing is envisioned to be the next generation of information technology (IT) evolution that depicts how computing needs of users can be fulfilled in the future IT industry (Rappa 2004). Its analogy is derived from the real world, where service providers maintain and supply utility services, such as electrical power, gas, and water to consumers. Consumers in turn pay service providers based on their rates of use of these services. Therefore, the underlying design of utility computing is based on a service-provision model, in which users (consumers) pay providers for using computing power only when they need it.

These developments are the realization of the vision of Leonard Kleinrock, one of the chief scientists of the original Advanced Research Projects Agency Network (ARPANET) project, which seeded the Internet, who said in 1969 (Kleinrock 2005): “As of now, computer networks are still in their infancy, but as they grow up and become sophisticated, we will probably see the spread of ‘computer utilities’ which, like present electric and telephone utilities, will service individual homes and offices across the country.”

Benefits of Utility Computing

The utility computing model offers a number of benefits to both service providers and users. From the provider’s perspective, actual hardware and software components are not set up or configured to satisfy a single solution or user, as in the case of traditional computing. Instead, virtualized resources are created and assigned dynamically to various users when needed. Providers can thus reallocate resources easily and quickly to users that have the highest demands. In turn, this efficient use of resources minimizes operational costs for providers, since they are now able to serve a larger community of users without letting unused resources get wasted. Utility computing also enables providers to achieve a better return on investment (ROI), such as total cost of ownership (TCO), since shorter times are now required to derive positive returns and incremental profits can be earned with the gradual expansion of infrastructure that grows with user demands.

For users, the most prominent advantage of utility computing is the reduction of IT-related operational costs and complexities. Users no longer need to invest heavily or encounter difficulties in building and maintaining IT infrastructures. Computing expenditures can now be modeled as a variable cost depending on the usage patterns of users,

instead of as a static cost of purchasing technology and employing staff to manage operations. Users neither need to be concerned about possible over- or underutilization of their own self-managed IT infrastructures during peak or nonpeak usage periods nor worry about being confined to any single vendor's proprietary technologies. With utility computing, users can obtain appropriate amounts of computing power from providers dynamically, based on their specific service needs and requirements. This is particularly useful for users who experience rapidly increasing or unpredictable computing needs. Such an outsourcing model thus provides increased flexibility and ease for users to adapt to their changing business needs and environments (Ross and Westerman 2004).

In today's highly competitive and rapidly changing market environment, business organizations aim to be more adaptive in their business and IT strategies, in order to stay ahead of other competitors (Figure 1). An adaptive organization requires enhanced IT processes and better resource utilization in order to deliver faster response, higher productivity, and lower costs (Figure 2). Therefore, there seems to be a potential to use utility computing models for business organizations to be more adaptive and competitive.

Potential of Grids as Utility Computing Environments

The aim of *Grid computing* is to enable coordinated resource sharing and problem solving in dynamic, multi-institutional virtual organizations (Foster, Kesselman, and Tuecke 2001). An infinite number of computing devices, ranging from high-performance systems such as supercomputers and clusters, to specialized systems such as visualization devices, storage systems, and scientific instruments, are logically coupled together in a *Grid* and presented as a single unified resource (Buyya, Cortes, and Jin 2001) to the user. Figure 3 shows that a Grid user can easily use these globally distributed Grid resources by interacting with a Grid resource broker. Basically, a Grid user perceives the Grid as a single huge virtual computer that provides immense computing capabilities, identical to an Internet user who views the World Wide Web as a unified source of content.

A diverse range of applications are currently or soon to be used on Grids, some of which include aircraft engine diagnostics, earthquake engineering, virtual observatory, bioinformatics, drug discovery, digital image analysis, high-energy physics, astrophysics, and multiplayer gaming

Figure 2: Goals of using adaptive solutions (Source: META Group 2004)

Figure 3: A generic view of a global Grid

Figure 4: Types of Grids and their focus

(Foster and Kesselman 2003). Grids can be primarily classified into the following types, depending on the nature of their emphasis (Krauter, Buyya, and Maheswaran 2002), as depicted in Figure 4:

- *Computational Grid*: Aggregates the computational power of globally distributed computers, e.g., TeraGrid (Reed 2003) and ChinaGrid (Jin 2004).
- *Data Grid*: Emphasizes on a global-scale management of data to provide data access, integration, and processing through distributed data repositories, e.g., LHC Computing Grid (Lamanna 2004) and GriPhyN (Deelman et al. 2002).
- *Application Service Provisioning (ASP) Grid*: Focuses on providing access to remote applications, modules, and libraries hosted on data centers or Computational Grids, e.g., NetSolve (Agrawal et al. 2003).
- *Interaction Grid*: Focuses on interaction and collaborative visualization between participants, e.g., Access Grid (Childers et al. 2000).
- *Knowledge Grid*: Aims toward knowledge acquisition, processing, management, and providing business analytics services driven by integrated data mining services, e.g., Italian KnowledgeGrid (Cannataro and Talia 2003) and Data Mining Grid (Cannataro, Talia, and Trunfio 2002).

- *Utility Grid*: Focuses on providing all the Grid services, including compute power, data, and services to end users as IT utilities on a subscription basis and the infrastructure necessary for negotiation of required quality of service (QoS), establishment and management of contracts, and allocation of resources to meet competing demands from multiple users and applications, e.g., Gridbus (Buyya and Venugopal 2004) and Utility Data Center (Graupner, Pruyne, and Singhal 2003).

These various types of Grids follow a layered design, with the Computational Grid as the bottommost layer and the Utility Grid as the topmost. A Grid on a higher layer uses the services of Grids that operate at lower layers in the design. For example, a Data Grid uses the services of Computational Grid for data processing and hence builds on it. In addition, lower-layer Grids focus heavily on infrastructural aspects, whereas higher-layer ones focus on users and QoS delivery. Accordingly, Grids are proposed as the emerging cyber infrastructure to power utility computing applications.

Grids offer a number of benefits such as:

- Transparent and instantaneous access to geographically distributed and heterogeneous resources
- Improved productivity with reduced processing time
- Provision of extra resources to solve problems that were previously unsolvable because of the lack of resources
- A more resilient infrastructure with on-demand aggregation of resources at multiple sites to meet unforeseen resource demand
- Seamless computing power achieved by exploiting underused or unused resources that are otherwise wasted
- Maximum utilization of computing facilities to justify IT capital investments
- Coordinated resource sharing and problem solving through virtual organizations (Foster, Kesselman, and Tuecke 2001) that facilitates collaboration across physically dispersed departments and organizations
- Service Level Agreement (SLA)-based resource allocation to meet QoS requirements
- Reduced administration effort with integration of resources as compared with managing multiple stand-alone systems

Layered Grid Architecture

The components that are necessary to form a Grid are shown in Figure 5. The layered Grid architecture organizes various grid capabilities and components such that high-level services are built using lower-level services. Grid economy (Buyya, Abramson, and Venugopal 2005) is essential for achieving adaptive management and utility-based resource allocation and thus influences various layers of the architecture:

- *Grid fabric software layer:* Provides resource management and execution environment at local Grid resources. These local Grid resources can be computers (e.g., desktops, servers, or clusters) running a variety of operating systems (e.g., UNIX or Windows), storage devices, and special devices such as a radio telescope or heat sensor. As these resources are administered by different local resource managers and monitoring mechanisms, there needs to be Grid middleware that can interact with them.
- *Core Grid middleware layer:* Provides Grid infrastructure and essential services, which consists of information services, storage access, trading, accounting, payment, and security. As a Grid environment is a highly dynamic one in which the location and availability of services are constantly changing, information services provide the means for registering and obtaining information about Grid resources, services, and status. Resource trading based on the computational economy approach is suitable given the complex and decentralized manner of Grids. This approach provides incentives for both resource providers and users to be part of the Grid community, and allows them to develop strategies to maximize their objectives. Security services are also critical to address the confidentiality, integrity, authentication, and accountability issues for accessing resources across diverse systems that are autonomously administered.
- *User-level middleware layer:* Provides programming frameworks and policies for various types of applications, and resource brokers to select appropriate and specific resources for different applications. The Grid

programming environment and tools should support common programming languages (e.g. C, C++, FORTRAN, and Java), a variety of programming paradigms (e.g., message passing [Gropp, Lusk, and Skjellum 1999] and distributed shared memory (DSM) [Nitzberg and Lo 1991]), and a suite of numerical and commonly used libraries. Resource management and scheduling should be transparent to the users such that processor time, memory, network, storage, and other resources in Grids can be used and managed effectively and efficiently using middleware such as resource brokers.

- *Grid applications layer:* Enables end users to use Grid services. Grid applications thus need to focus on usability issues so that end users can find them intuitive and easy to use. They should also be able to function on a variety of platforms and operating systems so that users can easily access them. Therefore, an increasing number of Web portals are being built, since they allow users to ubiquitously access any resource from anywhere over any platform at any time.

The design aims and benefits of Grids are analogous to those of utility computing, thus highlighting the potential and suitability of Grids to be used as utility computing environments. The current trend of implementing Grids based on open-standard service-based architectures to improve interoperability is a step toward supporting utility computing (Joseph and Fellenstein 2004). Even though most existing Grid applications are scientific research and collaboration projects, the number of Grid applications in business and industry-related projects is also gradually increasing. It is thus envisioned that the realization of utility computing through Grids will follow a similar course as that of the World Wide Web, which was first initiated as a scientific project but was later widely adopted by businesses and industries.

Challenges of Realizing Utility Computing Models

There are several challenges that need to be addressed in order to realize utility computing. One is that both

Figure 5: A layered Grid architecture (API = application programming interface)

providers and users need to redraft and reorganize their current IT-related procedures and operations to include utility computing (Ross and Westerman 2004). New IT policies need to be negotiated and agreed upon between providers and users; compared this with the previous situation, in which providers and users owned and controlled their stand-alone policies. Providers must also understand specific service needs and requirements of users in order to design suitable policies for them. Open standards need to be established to facilitate successful adoption of utility computing so that users and producers experience fewer difficulties and complexities in integrating technologies and working together, thus reducing associated costs. Table 1 lists some of the major computing standards organizations and the activities in which they are engaged.

With the changing demand of service needs from users, providers must be able to fulfill the dynamic fluctuation of peak and nonpeak service demands. Service contracts known as Service Level Agreements (SLAs) are used by providers to assure users of their level of service quality. If the expected level of service quality is not met, providers will then be liable for compensation and may incur heavy losses. Therefore, providers seek to maximize customer satisfaction by meeting service needs and minimize the risk of SLA violations (Buco et al. 2004).

Improved service-oriented policies and autonomic controls (Kephart and Chess 2003; Murch 2004) are essential for achieving this.

Other than managing the technological aspects of delivering computing services, providers also need to consider the financial aspects of service delivery. Financial risk management for utility computing (Kenyon and Cheliotis 2005) is comprised of two factors: delivery risk and pricing risk. Delivery-risk factors examine the risks concerned with each possible scenario in which a service can be delivered. Pricing-risk factors study the risks involved with pricing the service with respect to the availability of resources. Given shorter contract durations, lower switching costs, and uncertain customer demands in utility computing environments, it is important to have dynamic and flexible pricing schemes to potentially maximize profits and minimize losses for providers (Paleologo 2004).

There are also potential nontechnical obstacles to the successful adoption of utility computing, such as cultural and people-related issues that will require organizations to change their current stance and perceptions (Platform Computing 2003). The most worrying issues being perceived are loss of control or access to resources, risks associated with enterprise-wide deployment, loss or reduction of budget dollars, and reduced priority of projects. Thus, overcoming these nontechnical obstacles is

extremely critical and requires the dissemination of correct information to all levels of management with-in organizations to prevent the formation of misperceptions.

UTILITY GRIDS

This chapter focuses on the use of Grid technologies to achieve utility computing. An overview of how Grids can support utility computing is first presented through the architecture of Utility Grids. Then, utility-based resource allocation is described in detail at each level of the architecture. Finally, some industrial solutions for utility computing are discussed.

A reference service-oriented architecture for Utility Grids is shown in Figure 6. The key players in a Utility Grid are the Grid user, Grid resource broker, Grid middleware services, and Grid service providers (GSPs).

Grid users want to make use of Utility Grids to complete their applications. Refactoring existing applications is thus essential to ensure that these applications are Grid-enabled to run on Utility Grids (Kra 2004). The Grid user also needs to express the service requirements to be fulfilled by GSPs. Varying QoS parameters, such as deadline for the application to be completed and budget to be paid upon completion, are defined by different Grid users, thus resulting in dynamic fluctuation of peak and nonpeak service demands. The Grid resource broker then discovers appropriate Grid middleware services based on these service demand patterns and QoS requirements, and dynamically schedules applications on them at runtime, depending on their availability, capability, and costs. A GSP needs tools and mechanisms that support pricing specifications and schemes so they can attract users and improve resource utilization. They also require protocols that support service publication and negotiation, accounting, and payment.

The Grid resource broker comprises the following components:

- *Job control agent*: Ensures persistency of jobs by coordinating with schedule advisor for schedule generation, handling actual creation of jobs, maintaining job status, and interacting with users, schedule advisor, and deployment agent.
- *Grid explorer*: Interacts with Grid information service to discover and identify resources and their current status.
- *Schedule advisor*: Discovers Grid resources using the Grid explorer, and selects suitable Grid resources and assigns jobs to them (schedule generation) to meet users' requirements.
- *Trade manager*: Accesses market directory services for service negotiation and trading with GSPs based on resource selection algorithm of schedule advisor.
- *Deployment agent*: Activates task execution on the selected resource according to schedule advisor's instruction and periodically updates the status of task execution to job control agent.

Traditional core Grid middleware focuses on providing infrastructure services for secure and uniform access to distributed resources. Supported features include security, single sign-on, remote process management, storage access, data management, and information services. An example of such middleware is the Globus Toolkit (Foster and Kesselman 1997) which is a widely adopted Grid technology in the Grid community. Utility Grids require additional service-driven Grid middleware infrastructure that includes:

- *Grid market directory*: Allows GSPs to publish their services so as to inform and attract users.

Figure 6: A reference service-oriented architecture for Utility Grids (R = resource)

- *Trade server*: Negotiates with Grid resource broker based on pricing algorithms set by the GSP and sells access to resources by recording resource usage details and billing the users based on the agreed pricing policy.
- *Pricing algorithms*: Specifies prices to be charged to users based on the GSP's objectives, such as maximizing profit or resource utilization at varying times and for different users.
- *Accounting and charging*: Records resource usage and bills the users based on the agreed terms negotiated between Grid resource broker and trade server.

Figure 7 shows how services are assembled on demand in a Utility Grid. The application code is the legacy application to be run on the Utility Grid. Users first compose their application as a distributed application such as a parameter sweep using visual application composer tools (step 1). The parameter-sweep model creates multiple independent jobs, each with a different parameter. This model is well suited for Grid computing environments wherein challenges such as load volatility, high network latencies, and high probability of individual node failures make it difficult to adopt a programming approach that favors tightly coupled systems. Accordingly, a parameter-sweep application has been termed as a “killer application” for the Grid (Abramson, Giddy, and Kotler 2000).

Visual tools allow rapid composition of applications for Grids by hiding the associated complexity from the user. The user's analysis and QoS requirements are submitted to the Grid resource broker (step 2). The Grid resource broker first discovers suitable Grid services based on user-defined characteristics, including price, through the Grid information service and the Grid market directory (steps 3 and 4). The broker then identifies the list of data sources or replicas through a data catalog and selects the optimal ones (step 5). The broker also identifies the list of GSPs that provide the required application services using the application service provider (ASP)

catalog (step 6). The broker checks that the user has the necessary credit or authorized share to use the requested Grid services (step 7). The broker scheduler assigns and deploys jobs to Grid services that meet user QoS requirements (step 8). The broker agent on the Grid resource at the GSP then executes the job and returns the results (step 9). The broker consolidates the results before passing them back to the user (step 10). The metering system charges the user by passing the resource-usage information to the accounting service (step 11). The accounting service reports remaining resource share allocation and credit available to the user (step 12).

Layered Grid Architecture Realization

To enable Utility Grids, the Gridbus project (Buyya and Venugopal 2004) has offered open-source Grid middleware for various layers (as highlighted in Figure 8) that include:

- *Grid fabric software layer*: Libra, a utility-driven cluster scheduler that considers and enforces SLAs for jobs submitted into the cluster.
- *Core Grid middleware layer*: Alchemi, which is a .NET-based desktop Grid framework; Grid Market Directory, which is a directory publishing available Grid services; Grid Bank, which provides accounting, authentication, and payment facilities; and GridSim, which is an event-driven simulator that models Grid environments.
- *User-level middleware layer*: Gridbus broker, which selects suitable Grid services and schedules applications to run on them; Grid workflow engine, which provides workflow execution and monitoring on Grids; and Visual Parametric Modeler, which provides a graphical environment to parameterize applications.
- *Grid application layer*: Web portals such as Gridscape, which provides interactive and dynamic Web-based Grid monitoring portals, and G-Monitor, which manages execution of applications on Grids using brokers.

UTILITY-BASED RESOURCE ALLOCATION AT VARIOUS LEVELS

Utility-based resource allocation is essential at various levels of the Utility Grid in order to realize the utility computing model. This section examines the challenges involved in clusters, distributed storage, Computational Grid brokering, Data Grids, workflow scheduling, advanced reservation, and cooperative virtual organizations.

Clusters

A *cluster* is a type of parallel or distributed computer system, which consists of a collection of interconnected stand-alone computers working together as a single integrated computing resource (Buyya 1999; Pfister 1998). Clustering these stand-alone computers together has resulted in high-performance, high-availability, and high-throughput processing on a network of computers at a much lower cost than traditional supercomputing systems, thus resulting in *cluster computing* being a more viable choice as a supercomputing solution. As clusters are extensively used in data centers, which promise to provide managed computing, storage, and application services at low cost, the costs of ownership and maintenance need to be reduced. But, clusters are heavily focused on increasing peak performance using tens of thousands of power-hungry components, which is leading to intolerable operating cost and failure rates (Ge, Feng, and Cameron 2005). Thus, power-aware clusters have been built to

reduce power consumption by leveraging DVS (dynamic voltage scaling) techniques and using distributed performance-directed DVS scheduling strategies. Such clusters are able to gain similar performance, yet reduce the amount of power consumption.

Currently, service-oriented Grid technologies are used to enable utility computing environments in which the majority of Grid resources are clusters. Grid schedulers such as brokers and workflow engines can then discover suitable Grid resources and submit jobs to them on behalf of the users. If the chosen Grid resource is a cluster, these Grid schedulers then interact with the cluster resource management system (RMS) to monitor the completion of submitted jobs. The cluster RMS is a middleware that provides a uniform interface to manage resources, queue jobs, schedule jobs, and execute jobs on multiple compute nodes within the cluster. With a utility model, users can specify different levels of service needed to complete their jobs. Thus, providers and users have to negotiate and agree on SLAs that serve as contracts outlining the expected level of service performance. Providers can then be liable to compensate users for any service underperformance. So, the cluster RMS must be able to enable utility-driven cluster computing by supporting SLA-based resource allocation that can meet competing user demands and enforce their service needs.

Existing cluster RMSs need to be enhanced or extended to adopt utility-driven resource allocation rather than the current system-centric resource allocation that maximizes resource throughput and utilization of the

cluster. System-centric approaches assume that all job requests are equally important and thus neglect the actual levels of service required by different users. The cluster RMS should have the following components:

- *Request examiner*: Interprets the QoS parameters defined in the SLA.
- *Admission control*: Determines whether a new job request should be accepted or not. This ensures that the cluster is not overloaded with too many requests such that service performance deteriorates.
- *SLA based scheduler*: New service-oriented policies need to be incorporated to allocate resources efficiently based on service requirements.
- *Job monitor*: New measurement metrics need to be used to keep track of whether the execution progress of jobs meets the service criteria.
- *Accounting*: Maintains the actual usage of resources so that usage charges can be computed. Usage information can also be used to make better resource-allocation decisions.
- *Pricing*: Formulate charges for meeting service requests. For example, requests can be charged based on submission time (peak/off-peak), pricing rates (fixed/variant), or availability of resources (supply/demand).
- *Job control*: Enforces resource assignment for executing requests to fulfill specified service needs.

The key design factors and issues for a utility-driven cluster RMS can be addressed from five perspectives (Yeo and Buyya 2006):

- *Market model*: Considers market concepts present in real-world human economies to be applied for service-oriented resource allocation in clusters to deliver utility.
- *Resource model*: Addresses architectural framework and operating environments of clusters that need to be conformed.
- *Job model*: Examines attributes of jobs to ensure that various job types with distinct requirements can be fulfilled successfully.
- *Resource allocation model*: Analyzes factors that can influence the resource-assignment outcome.
- *Evaluation model*: Assesses the effectiveness and efficiency of the cluster RMS in satisfying the utility model.

There is therefore growing research interest in formulating effective service-oriented resource allocation policies to satisfy the utility model. Computation-at-risk (CaR) (Kleban and Clearwater 2004) determines the risk of completing jobs later than expected based on either the makespan (response time) or the expansion factor (slowdown) of all jobs in the cluster. Cluster-On-Demand (Irwin, Grit, and Chase 2004) reveals the significance of balancing the reward against the risk of accepting and executing jobs, particularly in the case of unbounded penalty. A QoS-based scheme for parallel job scheduling (QoPS) (Islam et al. 2004) incorporates an admission control to guarantee the deadline of every accepted job

by accepting a new job only if its deadline can be guaranteed without violating the deadlines of already accepted jobs. LibraSLA (Yeo and Buyya 2005) accepts jobs with hard deadlines only if they can be met, and accepts jobs with soft deadlines depending on their penalties incurred for delays. Another work (Popovici and Wilkes 2005) addresses the difficulties encountered by service providers when they rent resources from resource providers to run jobs accepted from clients. These include difficulties such as which jobs to accept, when to run them, and which resources to rent to run them. It analyzes the likely impact on these difficulties in several scenarios, including changing workload, user impatience, resource availability, resource pricing, and resource uncertainty.

Distributed Storage

Storage plays a fundamental role in computing as it is present in many key components, from registers and random access memory (RAM) to hard disk drives and optical disk drives. Combining storage with networking has created a platform for distributed storage systems (DSSs). The wide proliferation of the Internet has created a global network—a platform with innovative possibilities such as offering access to storage as a utility. DSSs functioning in a global environment support sharing of storage across geographic, institutional, and administrative boundaries. The network speed (bandwidth and latency) and usage load impact the speed of remote storage access; however, they can be overcome through smart access management techniques such as demand prediction, preloading, and caching. The key benefits of such DSS are that it: (1) enables aggregation of storage resources from different sources to create mass storage systems at lower cost, (2) enhances reliability of storage through replication, (3) supports disaster management and recovery through replication of content across multiple sites, (4) provides the ability to offer access to storage as utility services, which in turn reduces the cost of ownership and management of storage systems for end users, and (5) allows organizations to barter or harness each other's storage systems for transparent sharing and preservation of digital assets such as e-books, e-music, e-journals, and scientific experimental data.

Some prominent examples of DSS are Parallel Virtual File System (PVFS) (Ligon and Ross 2001), General Parallel File System (GPFS) (Barkes et al. 1998), and Google File System (GFS) (Ghemawat, Gobioff, and Leung 2003). A key challenge in DSS is ensuring that storage services are shared fairly among users and that providers are offered incentives for making storage services available. One way to achieve this is applying economic principles. Examples of DSSs that apply economic principles to manage various aspects of operational behavior include: Mungi, which manages storage quota; Mojo Nation, which instills cooperative behavior; Stanford Archival Repository (SAR), which encourages the sharing of storage services and exchanges; and OceanStore, which provides utility storage. SAR (Cooper and Garcia-Molina 2002) is the Stanford Archival Repository, a bartering storage system for preserving information. Institutions that have common requirements and storage infrastructure can

use the framework to barter with each other for storage services. For example, libraries may use this framework to replicate their archives among one another for the purpose of preservation. OceanStore (Kubiatowicz et al. 2000) is a globally scalable storage utility, providing paying users with a durable, highly available storage service by utilizing nontrusted infrastructure. Mungi (Heiser et al. 1998) is a single-address-space operating system (SASOS), which uses economic principles to manage storage quota. Mojo Nation (Wilcox-O'Hearn 2002) uses digital currency, *Mojo*, to encourage users to share resources on its network. Users that contribute services are rewarded with *Mojo*, which can then be traded for services. Storage Exchange (Placek and Buyya 2006) applies a double auction (DA) market model, allowing storage services to be traded in a global environment.

Treating storage as a tradable commodity provides incentives for users to participate in the federating and sharing of their distributed storage services. However, there are still some challenges that need to be overcome before storage utility can be fully realized:

- *Federate*: A plethora of heterogeneous storage systems exist; creating a homogenous interface is a key step in federating storage.
- *Share*: Ensuring that distributed storage resource is shared fairly among users and that no single user can deny access to others, accidentally or otherwise.
- *Security*: Operating on nontrusted infrastructure requires the use of cryptographic mechanisms in order to enforce authentication and prevent malicious behavior.
- *Reliability*: Storage medium and network failures are common in a global storage infrastructure, and therefore mechanisms of remote replicas and erasure codes need to be used to ensure that persistent reliable access to stored data is achieved.

Although the challenges are many, the weight of incentives and future from realizing a globally distributed storage utility ensure the continuing research and development in this area:

- *Monetary gain*: Institutions providing storage services (providers) are able to better use existing storage infrastructure in exchange for monetary gain. Institutions consuming these storage services (consumers) have the ability to negotiate for storage services as they require them, without needing to incur the costs associated with purchasing and maintaining storage hardware.
- *Common objectives*: There may be institutions that wish to exchange storage services between themselves because of a mutual goal such as preservation of information (Cooper and Garcia-Molina 2002).
- *Spikes in storage requirements*: Research institutions may require temporary access to mass storage (Vazhkudai et al. 2005), such as needing access to additional storage to temporarily store data generated from experiments that are carried out infrequently. In exchange, institutions may provide access to their storage services for use by others when they are not being used.

- *Donate*: Institutions may wish to donate storage services, particularly if these services are going to a noble cause.
- *Autonomic storage*: Development of a framework to support future autonomic storage systems will allow agents to broker storage on an as-needed basis.

Computational Grid Brokering

A Computational Grid broker acts as an agent for the user in Computational Grids by performing various tasks such as resource discovery, job scheduling, and job monitoring. To determine which resources to select, the broker needs to take into account various attributes from both the user perspective, such as resource requirements of the application, and the resource perspective, such as resource architecture and configuration, resource status (available memory, disk storage, and processing power), resource availability, network bandwidth, resource workload, and historical performance.

However, the Computational Grid broker needs to consider additional service-driven attributes such as QoS requirements specified by users in order to support the utility model. For example, users may specify a deadline for the completion of their application. The user may also state the maximum price to be paid for the completion. With the user's request of deadline and price for an application, the broker tries to locate the most suitable resources. Thus, during resource discovery, the broker also needs to know the costs of resources that can be obtained from a Grid market directory service and are set by GSPs. The broker must be able to negotiate with GSPs to establish an agreed price for the user, before selecting the most suitable resources with the best price based on the provided QoS. For instance, a more relaxed deadline should be able to obtain cheaper access to resources and vice versa. So, different users often have varying prices based on their specific needs. To locate the most suitable resources, we need new scheduling algorithms that take into consideration the application processing requirements, Grid resource dynamics, users' QoS requirements, such as the deadline and budget, and their optimization preferences.

The Nimrod-G resource broker (Abramson, Buyya, and Giddy 2002) and Gridbus Grid service broker (Venugopal, Buyya, and Winton 2006) are examples of service-oriented Computational Grid brokers for parameter-sweep applications. Both brokers schedule jobs based on economic principles (through the budget that the user is willing to pay) and a user-defined QoS requirement (the deadline within which the user requires the application to be completed). Nimrod-G implements four adaptive algorithms for scheduling compute-intensive parameter sweep applications:

- *Cost optimization*: Execution time is within the specified deadline and execution cost is the cheapest.
- *Time optimization*: Execution time is the shortest and execution cost is within the specified budget.
- *Cost-time optimization*: Similar to cost optimization, but if there are multiple resources with the same cost,

it applies time optimization so that execution time is the shortest with the same cost.

- *Conservative time optimization:* Similar to cost-time optimization, but ensures that each unprocessed job in the parameter-sweep application has a minimum budget per job.

The Gridbus broker extends cost and time optimization to schedule distributed data-intensive applications that require access to and processing of large datasets stored in distributed repositories.

Data Grids

Data comprise one of the most important entities within any IT infrastructure. Therefore, any utility computing platform must be able to provide secure, reliable, and efficient management of enterprise data and must be able to abstract the mechanisms involved. One of the key factors in the adoption of Grids as a utility computing platform is the creation of an infrastructure for storing, processing, cataloging, and sharing the ever-expanding volumes of data that are being produced by large enterprises such as scientific and commercial collaborations. This infrastructure, commonly known as “Data Grids,” provides services that allow users to discover, transfer, and maintain large repositories of data. At the very minimum, a Data Grid provides a high-performance and reliable data-transfer mechanism and a data-replica-management infrastructure. Data-manipulation operations in a Data Grid are mediated through a security layer that, in addition to the facilities provided by the general Grid security services, also provides specific operations such as managing access permissions and encrypted data transfers.

In recent years, the Grid community has adopted the Open Grid Service Architecture (OGSA) (Foster et al. 2002) which leverages Web service technologies such as XML and SOAP to create Grid services that follow standard platform-independent mechanisms for representation, invocation, and data exchange. A subgroup of OGSA deals with providing basic interfaces, called “data services,” that describe data and the mechanisms to access it. Data services virtualize the same data by providing multiple views that are differentiated by attributes and operations. They also enable different data sources, such as legacy databases, data repositories, and even spreadsheets to be treated in the same manner via standard mechanisms (Antonioletti et al. 2004).

Virtualization of data creates many possibilities for its consumption, enabled by the coupling of Grid services to enable applications such as data-intensive workflows. Already, projects such as Virtual Data Grid (VDG) (Foster et al. 2003) represent data not in terms of physical storage but as results of computational procedures. This has at least two possibilities for users: the ability to determine the provenance of data (i.e. determine how it was produced and if it is valid) and the ability to reuse the data products in future experiments in which the same procedures with the same inputs are involved. Pegasus (Deelman et al. 2003) is a workflow management system from the GriPhyN project that uses the VDG to reduce workflows by substituting previously generated data whenever

possible. A similar procedure is followed by Storage Resource Broker (SRB) (Moore, Rajasekar, and Wan 2005), which uses stored procedures in its SRB Matrix to reduce dataflow graphs. Therefore, data virtualization isolates the users from the physical Data Grid environment.

Data virtualization is an important technology for creating an information-rich utility computing environment that is able to provide its users with the following abilities:

- Seamlessly discover and use available data services
- Plan ahead for future requirements and take preemptive action
- Create dynamic applications by combining services

In such an environment, QoS parameters associated with a data service play an important role in data service discovery. Such parameters include the amount of data, permissions associated with access and modification, available bandwidth to storage locations, and relevance. Relevance of data can be determined from the provenance data that describes the procedures used for producing the data. Planning, scheduling, and reserving resources in advance is conducted by resource brokers that take QoS parameters into account while selecting data sources and storage locations.

Workflow Scheduling

With the advent of Grid and application technologies, scientists and engineers are building more and more complex applications to manage and process large data sets, and execute scientific experiments on distributed resources. Such application scenarios require means for composing and executing complex workflows. Workflows are concerned with the automation of procedures whereby files and data are passed between participants according to a defined set of rules to achieve an overall goal (Hollinsworth 1995). A workflow management system defines, manages, and executes workflows automatically on computing resources. Imposing the workflow paradigm for application composition on Grids offers several advantages (Spooner et al. 2005), such as:

- Ability to build dynamic applications which orchestrate distributed resources
- Utilization of resources that are located in a particular domain to increase throughput or reduce execution costs
- Execution spanning multiple administrative domains to obtain specific processing capabilities
- Integration of multiple teams involved in managing different parts of the experiment workflow, thus promoting interorganizational collaborations

QoS support in workflow management is required by many workflow applications. For example, a workflow application for planning maxillofacial surgery (Berti et al. 2003) needs results to be delivered before a certain time. However, QoS requirements cannot be guaranteed in a conventional Grid where resources provide only best effort services. Therefore, there is a need to have Utility

Grids that allow users to negotiate with service providers on a certain service agreement with the requested QoS.

In general, scheduling workflows on Utility Grids is guided by users' QoS expectations. Workflow management systems are required to allow the user to specify their requirements, along with the descriptions of tasks and their dependencies using the workflow specification. In general, QoS constraints express the preferences of users and are essential for efficient resource allocation. QoS constraints can be classified into five dimensions (Yu and Buyya 2005): time, cost, fidelity, reliability, and security. *Time* is a basic measure of performance. For workflow systems, it refers to the total time required to execute a workflow. *Cost* represents the cost associated with the execution of workflows, including the cost of managing workflow systems and usage charge of Grid resources for processing workflow tasks. *Fidelity* refers to the measurement related to the quality of the output of workflow execution. *Reliability* is related to the number of failures for execution of workflows. *Security* refers to confidentiality of the execution of workflow tasks and trustworthiness of resources.

Several new issues arise from scheduling QoS-constrained workflows on Utility Grids:

- In general, users would like to specify a QoS constraint for the entire workflow. It is required that the scheduler determine a QoS constraint for each task in the workflow, such that the global QoS is satisfied.
- The scheduler is required to be adaptive to evaluate a proposed SLA and negotiate with a service provider for one task with respect to its current accepted set of SLAs and expected return of unscheduled tasks.
- The description language and monitoring mechanism for QoS-based workflows will be more complex as compared with traditional workflow scheduling.

To date, several efforts have been made toward QoS-aware workflow management. Web Services Agreement (WS-Agreement) (Andrieux et al. 2004) allows a resource provider and a consumer to create an agreement on the expected service qualities between them. Grid Quality of Service Management (G-QoS) (Al-Ali et al. 2004) provides Grid services in which workflow schedulers can negotiate and reserve services based on certain quality levels. The Vienna Grid Environment (VGE) (Benkner et al. 2004) develops a dynamic negotiation model that facilitates workflow schedulers to negotiate various QoS constraints with multiple service providers. It also extends the Business Process Execution Language (BPEL) (Brandic et al. 2005) to support QoS constraint expression. A QoS-based heuristic for scheduling workflow applications can be found in Menascé and Casalicchio (2004). The heuristic attempts to assign the task into least expensive computing resources based on assigned time constraint for the local task. A cost-based scheduling algorithm (Yu, Buyya, and Tham 2005) minimizes the cost, while meeting the deadline of the workflow by distributing the deadline for the entire workflow into sub-deadlines for each task. More recently, budget-constrained workflow scheduling has been developed by Yu and Buyya (2006). It uses

genetic algorithms to optimize workflow execution time while meeting the user's budget.

However, supporting QoS in the scheduling of workflow applications is still at a very preliminary stage. There is a need for many advanced capabilities in workflow systems and resource allocation such as support of cyclic and conditional checking of workflow structure, adaptive scheduling based on dynamic negotiation models, and advanced SLA monitoring and renegotiation.

Advanced Reservation

In existing Grid systems, incoming jobs to resources are scheduled via either space-shared or time-shared mode. The space-shared mode runs jobs based on their submission times; similar to first-come, first-served (FCFS), whereas the time-shared mode allows multiple executions of jobs; hence, it behaves like a round-robin approach. With a Utility Grid, jobs can be prioritized based on users' QoSs by a resource scheduler. However, a Utility Grid is not necessarily able to handle high-priority jobs or guarantee reliable service. Therefore, *advance reservation* needs to be introduced in a Utility Grid system to secure resources prior to their execution.

Advanced reservation (AR) is a process of requesting resources for use at a specific time in the future (Smith, Foster, and Taylor 2000). Common resources that can be reserved or requested are processors, memory, disk space, and network bandwidth, or a combination of any of these. The main advantage of AR is that it guarantees the availability of resources to users and applications at specific times in the future. Hence, from the user's perspective:

- Jobs can be executed straight away at a specified time rather than being held up in a queue by other jobs. This is a highly desirable approach for executing workflow applications that have one or more dependencies.
- Dropouts in a network transfer, which is not an option in multimedia streaming applications such as videoconferencing, can be avoided.

Combining utility computing with AR allows resource providers to specify criteria and requirements of usage. In addition, resource providers can match and satisfy a user's QoS. Utility computing applies to different stages of AR (Sulistio and Buyya 2004) as follows:

- *Requesting a new reservation slot:* A user asks a resource about the availability of a reservation slot by giving details such as start time, duration, and number of processors. A resource can then either accept the request or reject it if the slot is already booked. Both the user and resource can continue negotiating until they reach an agreement—i.e. to accept or not to accept.
- *Modifying an existing reservation slot:* A user or a resource can request to modify an existing reservation slot. Modification is used as a way to shorten or extend the duration of a reservation. If a user's jobs are running longer than expected, extending the duration is needed to prevent the jobs from being preempted by a resource. A user can request to shorten a reservation if jobs have finished, in order to save some costs.

- *Canceling an existing reservation slot:* A user or a resource can request to cancel an existing reservation slot. However, this can be done only when both parties have agreed beforehand. Canceling a reservation before it starts can easily be agreed to by a resource. However, some resource providers may not allow the cancellation of a reservation once it has started.

Cooperative Virtual Organizations

The concept of the virtual organization (VO) is crucial to the Grid. In current Grid collaborations, physical organizations engage in projects and alliances such as joint ventures that require shared access to compute and data resources provided by their members. The model adopted for such endeavors is that of a VO, in which resource providers and users are organized in a structure that may comprise several physical organizations. VOs may vary in several ways, such as scope, dynamism, and purpose, even though they pose similar challenges regarding their formation, operation, and dissolution (Patel et al. 2005).

Over the years, applications and compute and data resources have been virtualized to enable the utility model for business processes. With regard to the creation of a VO, it may be assumed that a VO is formed because of the need from a business process or some project. Despite the virtualization provided by Grid technologies, organizations may have difficulties in expressing their needs and requirements to their potential partners. Additional challenges are the selection of partners and the establishment of trust at a level that allows the automated creation of VOs (Dimitrakos, Golby, and Kearney 2004). However, to enable the utility model in VOs, issues regarding the responsive or even the automated creation of VOs need to be tackled.

The operational phase of a VO is also a complex task. Resource sharing in VOs is conditional and rule-driven. Also, the relationship in some VOs is peer-to-peer. To complicate matters further, the collection of participating entities is dynamic (Joseph, Ernest, and Fellenstein 2004). This scenario complicates tasks such as the negotiation of SLAs among the participants of the VO or between the participants and the VO itself. Furthermore, the reconciliation, management, and enforcement of resource usage control policies in the VO poses several challenges as presented in Dumitrescu, Wilde, and Foster (2005). For example, a simple model for providing resources as utilities in VOs requires the presence of a trusted VO manager. Resource providers are committed to deliver services to the VO according to contracts established with the VO manager. The manager is therefore responsible for assigning quotas of these resources to VO groups and users based on some VO policy. Users are allowed to use services according to these quotas and the VO policy. However, in this context, the delivery of compute and data resources in a utility-model to VO users and groups makes tasks such as enforcement of policies in a VO level and accounting difficult.

A simple model in a VO that follows a peer-to-peer sharing approach is of best effort, in which “you give what you can and get what others can offer.” A more elaborate model, in which a VO manager does not exist, allows the

delivery of services following a “you get what you give” approach (Wasson and Humphrey 2003). Other approaches require multilateral agreements among the members of the VO and give rise to challenges in the enforcement of resource usage policies, as described before.

Current works have not focused on aspects related to the dissolution of VOs, since this problem involves issues that are more legal and social rather than technical. Hence, the delivery of compute resources as a utility in VOs requires the investigation and solving of these problems related to various aspects of a VO. Automation and responsiveness are also required in every stage of the life cycle of a VO.

INDUSTRIAL SOLUTIONS FOR UTILITY COMPUTING

Various commercial vendors have launched industrial solutions to support utility computing. Competing marketing terms are used by different vendors even though they share the same vision of providing utility computing. This section discusses four major industrial solutions, as listed in Table 2: HP's Adaptive Enterprise, IBM's E-Business On Demand, Oracle's On Demand, and Sun Microsystems's Sun Grid. All four solutions use Grids as the core enabling technology.

HP Adaptive Enterprise

The vision of HP's Adaptive Enterprise (HP 2005) is to synchronize the business and IT processes in an enterprise in order to allow it to benefit from changes in market demands. IT processes are coordinated through the Adaptive Enterprise architecture, which comprises two dimensions: IT management and IT service capabilities. The IT management dimension involves:

- *IT business management:* Long-term IT strategies such as asset management, customer and supplier relationship management, and project portfolio management need to be developed.
- *Service delivery management:* Various operational aspects of service delivery such as availability, cost, capacity, performance, security, and quality need to be considered.
- *Service delivery:* IT services need to be provided to users by highly automated systems.

The IT service capabilities dimension that is addressed under both service delivery management and service delivery in the IT management dimension consists of:

- *Business services:* Represent top-level services related to business processes such as the composition of workflows.
- *Information services:* Consolidate and manipulate information for business services that are independent from application services.
- *Application services:* Automate and handle the processing of applications.

Table 2: Some Major Industrial Solutions for Utility Computing

Vendor	Solution and Web Site	Brief Description	Core Enabling Technology and Web Site
HP	Adaptive Enterprise www.hp.com/go/adaptive	Simplifies, standardizes, modularizes, and integrates business processes and applications with IT infrastructures to adapt effectively in a changing business environment.	Grids www.hp.com/go/grid
IBM	E-Business On Demand www.ibm.com/ondemand	Performs on-demand business processes that include research and development, engineering and product design, business analytics, and enterprise optimization.	Grids www.ibm.com/grid
Oracle	On Demand www.oracle.com/ondemand	Standardizes and consolidates servers and storage resources to automate IT process management.	Grids www.oracle.com/grid
Sun Microsystems	Sun Grid www.sun.com/service/sungrid	Offers computing power pay-as-you-go service utility by charging users \$1 for every hour of processing.	Grids www.sun.com/software/grid

- *Infrastructure services:* Create a common infrastructure platform to host the application, information, and business services.

The Adaptive Enterprise architecture also defines four design principles that are to be realized for an enterprise to become more adaptive:

- *Simplification:* Complex IT environments can be streamlined through application integration, process automation, and resource virtualization to facilitate easier management and faster response.
- *Standardization:* Standardized architectures and processes enable easier incorporation of new technologies, improves collaboration, and saves cost.
- *Modularity:* Smaller reusable components can be deployed faster and more easily, increasing resource sharing and reducing cost.
- *Integration:* Dynamic linking of business processes, applications, and infrastructure components enhance agility and cost efficiency.

Grid technologies enable the successful implementation of the Adaptive Enterprise architecture to link IT infrastructure dynamically to business processes by fulfilling the following design rules:

- *Service-oriented architecture (SOA):* Grid services are defined based on OGSA (Foster et al. 2002), an open standard that leverages Web services to allow large-scale collaboration across the Internet.
- *Virtualization:* Grids harness a large pool of resources that can be shared across applications and processes to meet business demands.
- *Model-based automation:* Grid technologies integrate standalone resources and automate services, thus simplifying the process of deployment, management, and maintenance.

HP customizes the Globus Toolkit (Foster and Kesselman 1997) as the Grid infrastructure for its platforms. The Grid solutions offered by HP and its partners are listed in Table 3.

IBM E-Business On Demand

IBM's *E-business On Demand* (IBM 2003) aims to improve the competitiveness and responsiveness of businesses through continuous innovation in products and services. To achieve this aim, E-Business On Demand optimizes the following business processes:

- *Research and development*: New innovative products and services need to be researched and developed quickly to make an impact in the highly competitive market.
- *Engineering and product design*: Products and services need to be well-engineered and designed to meet customers' requirements.
- *Business analytics*: Swift and accurate business decisions need to be made based on market performance data in order to remain a market leader.
- *Enterprise optimization*: Stand-alone resources at various global branches need to be integrated so that workload can be distributed evenly and resources used fully to satisfy demand.

E-business On Demand targets numerous industries, including:

- *Automotive and aerospace*: Collaborative design and data-intensive testing
- *Financial services*: Complex scenario simulation and decision-making
- *Government*: Coordinated operation across civil and military divisions and agencies
- *Higher education*: Advanced compute and data-intensive research
- *Life sciences*: Biological and chemical information analysis and decoding

IBM applies four core enabling technologies for E-Business On Demand: Grid computing, autonomic computing, open standards, and integration technologies. Grid technologies acts as the key component to provide the flexibility and efficiency required for various E-Business On Demand environments:

- *Research and development*: Highly compute- and data-intensive research problems can be solved with lower cost and shorter time by harnessing extra computational and data resources in a Grid.
- *Engineering and product design*: Industry partners are able to collaborate by sharing resources and coordinating engineering and design processes through VOs and open standards-based Grid architecture.
- *Business analytics*: Heavy data analysis and processing can be sped up with extra computational and data resources so that results are derived in time for decision-making.
- *Enterprise optimization*: Virtualization and replication using Grid technologies ensures that underutilized resources are not wasted, but are instead used for back-up and recovery purposes.

The core component that IBM deploys for its Grid infrastructure is called the IBM Grid Toolbox, which is an enhanced version of the Globus Toolkit (Foster and Kesselman 1997). Table 4 lists Grid solutions that are available by IBM and its partners. IBM provides a general integrated Grid solution offering, called "Grid and Grow," for interested customers to easily deploy and sample Grid technologies. In addition, it has created customized Grid offerings for specific industries and applications to drive E-business On Demand.

Oracle On Demand

Oracle's On Demand aims to enable customers to focus on more strategic business objectives by improving their IT performance and maximize the return on investment in four areas:

- *Quality:* A comprehensive and configurable set of services specifically designed to improve IT performance will be continuously delivered.
- *Cost:* IT expenses are more easily predicted and lower, as there is no need to spend on additional unexpected repairs and upgrades.
- *Agility:* The offered service is flexible and can be tailored to satisfy changing complexities, environments, and business needs.
- *Risk:* Service level commitments guarantee problem resolution, enhancements, and expansions to maximize accountability.

Oracle's On Demand is implemented using Grid solutions through three basic steps:

- *Consolidation:* Hardware, applications, and information can be shared across multiple data centers.
- *Standardization:* Using common infrastructure, application, and information services bridges the gap between various servers, storages, and operating systems.
- *Automation:* Less system administration work is required, as multiple resources can be managed concurrently and more easily.

Table 5 shows the Grid solutions from Oracle and its partners. Oracle Database 10g is the first database designed for Grid computing and offers data-provisioning capabilities, such as detaching part of a database and attaching it to another database without unloading and reloading.

Sun Microsystems Sun Grid

Sun Microsystems's Sun Grid aims to provide affordable commodity-based computing power pay-as-you-go service. Sun Grid currently supports three types of compute utility service (see Table 6 for comparison):

- *Compute utility:* A standard offering that provides instant deployment for anyone with Internet access at \$1 per hour of processing.
- *Commercial utility:* A single-tenant standard offering in a multitenant hosting center that targets medium and large enterprises.
- *Variable cost infrastructure:* A customized modular offering and single-tenant utility model for large enterprises and system integrators.

The Sun Grid compute utility (Sun Microsystems 2006 January) provides a golden opportunity for non-IT users to make use of utility computing by providing a simple and easy to use Web interface that hides the complex Grid technologies involved. Given this assumption of a simple utility computing environment, the Sun Grid compute utility has several limitations:

- Submitted applications must be able to execute on the Solaris 10 operating system.
- Submitted applications must be self-contained and scripted to work with Sun N1 Grid Engine (Gentzsch 2001) software without requiring interactive access.
- Submitted applications have to be implemented using standard object libraries included with Solaris 10 Operating system or user libraries packaged with the executable file.
- The application can obtain finer control over compute resources through the interfaces provided by the Sun N1 Grid Engine software.
- The total maximum size of applications and data must be less than 10 GB.

Table 6: Comparison of Sun Grid Compute Utility Services

Comparison	Sun Grid Compute Utility Services		
	Compute Utility	Commercial Utility	Variable Cost Infrastructure
Access	Portal	Dedicated	Customer or system integrator hosted
Availability	Instantaneous	Short notice	Longer-term contract
Scheduling	No reservation	Time-based reservation	Dedicated or time-based reservation
Pricing	All-inclusive \$1/CPU-hour	Negotiated \$/CPU-hour	Negotiated
Business terms	Standard	Service level	Capacity provisioning
Technology	Solaris 10 $\times$ 64	Solaris 10 $\times$ 64 or Redhat Linux	Menu of options
Storage	10-GB standard	Customer defined	Menu of options

- Applications and data can be uploaded only through the Web interface and may be packaged into compressed ZIP files of less than 100 MB each.

Grid technologies are used for the Sun Grid compute utility with the following compute node configuration:

- 8 GB of memory
- Solaris 10 operating system
- Sun N1 Grid Engine 6 software for resource management of compute nodes
- Grid network infrastructure built on Gigabit Ethernet
- Web-based portal for users to submit jobs and upload data
- 10 GB of storage space for each user

Industries that are targeted by the Sun Grid compute utility consist of:

- *Energy*: Reservoir simulations and seismic processing

- *Entertainment/Media*: Digital content creation, animation, rendering, and digital asset management
- *Financial services*: Risk analysis and Monte Carlo simulations
- *Government education*: Weather analysis and image processing
- *Health sciences*: Medical imaging, bioinformatics, and drug development simulations
- *Manufacturing*: Electronic design automation, mechanical computer-aided design, computational fluid dynamics, crash-test simulations, and aerodynamic modeling

Sun Microsystems, Gridwise Tech, and the Globus project have been collaborating in the joint development of interfaces between Sun Grid solutions and the Globus Toolkit (Gridwise Tech 2006). Table 7 shows Grid solutions that are developed by Sun Microsystems and its partners.

CONCLUSION

In this chapter, the utility computing model and its vision of being the next generation of the IT evolution is introduced. The utility computing model is significantly different from traditional IT models, and thus requires organizations to amend their existing IT procedures and operations toward this outsourcing model so as to save costs and improve quality. There is also increasing emphasis on adopting Grid computing technologies to enable utility computing environments.

This chapter has focused on the potential of Grids as utility computing environments. A reference service-oriented architecture of Utility Grids has been discussed, along with how services are assembled on demand in the Utility Grid. The challenges involved in utility-based resource allocation at various levels of the Utility Grid are then examined in detail. With commercial vendors rapidly launching utility computing solutions, industrial solutions by four pioneer vendors (HP, IBM, Oracle, and Sun Microsystems) and their realization through Grid technologies are also presented.

For recent advances in Grid computing technologies and applications, readers are recommended to browse the proceedings of CCGrid (International Symposium on Cluster Computing and the Grid (CCGrid) 2001), Grid (International Conference on Grid Computing (Grid) 2000), and e-Science (International Conference on e-Science and Grid Computing (e-Science) 2005) conference series organized by the IEEE Technical Committee on Scalable Computing (TCSC) (2005).

ACKNOWLEDGEMENT

The authors thank Hussein Gibbins and the anonymous reviewers for their comments. This work is partially supported through the Australian Research Council (ARC) Discovery Project grant.

GLOSSARY

Adaptive Enterprise: An organization that is able to adjust and benefit according to the changes in its operating environment.

Grid Computing: A model allowing organizations to access a large quantity of remotely distributed computing resources on demand.

Market-Based Resource Allocation: Assignment of resources based on market supply and demand from providers and users.

Middleware: Software designed to interface and link separate software and/or hardware.

On Demand Computing: Computing services that can be accessed when required by the user.

Service Level Agreement (SLA): A contract agreed upon between a service provider and a user that formally specifies service quality that the provider is required to provide.

Service-Oriented Architecture (SOA): An architectural framework for the definition of services that are able to fulfill the requirements of users.

Utility Computing: A model whereby service providers offer computing resources to users only when the users need them and charges the users based on usage.

Virtual Organization (VO): A temporary arrangement formed across physically dispersed departments and organizations with a common objective to facilitate collaboration and coordination.

INTRODUCTION

The emergence of file-sharing systems such as Napster and Gnutella make the term *peer-to-peer* (P2P) popular. The benefits and challenges of such network architectures are realized by network operators and users. Their cost-effective resource aggregation capability, together with many other benefits, has motivated many new developments and products. Today, file sharing, content distribution, distributed computing, instant messaging, Internet telephony and videoconferencing, and ad hoc networking are all taking advantage of P2P network architectures. This chapter summarizes the network architectures that use the P2P concept.

We start with a discussion of what a P2P network is in the section on Definitions. Collections of the existing definitions of a P2P network are listed. Although there is no single concise definition of a P2P network, these definitions give us an informal description of a P2P network. Such an open mind is favorable, since new technologies can be accommodated as they are introduced.

An analysis of the benefits and limitations of P2P networks is given in the section on Benefits and Limitations of P2P Networks. Compared to centralized networks, P2P networks benefit from cost sharing and reduction, scalability, resource aggregation and interoperability, robustness improvement, increased autonomy, anonymity and privacy, enhanced dynamics, ad hoc communication, and collaboration. However, P2P networks are limited by their manageability, security, and service guarantee capability. It has been observed that P2P networks have limited methods to prevent cheating and selfish behaviors.

To present a general framework, we use a conceptual layered architecture to illustrate key building blocks in a P2P network in the section on P2P Network Architecture. The abstract reference P2P network architecture consists of three layers: the base overlay layer, the middleware layer, and the application layer. The base overlay layer provides peer discovery, overlay network construction, and application-level multicast. The middleware layer offers distributed search, publish and subscribe, security, distributed indexing, distributed directory, metadata, and scheduling. The application layer includes distributed communication and collaboration, file sharing, content

distribution, distributed storage, and massively parallel computing. P2P network implementations use very diversified architectures. Some P2P networks are developed as single applications, possibly using proprietary implementations. Some P2P networks provide software modules that can be used to compose other applications. The three-layer reference P2P network architecture captures the major functional characteristics of P2P networks. However, it does not imply that a P2P network has to strictly follow the reference architecture.

This chapter focuses on the architectural aspects; Chapter 145 is about P2P network applications. Although ad hoc networking extensively uses P2P network architecture, we do not cover ad hoc networking in this chapter, since other chapters discuss this concept.

DEFINITIONS

The term *client* refers to a process using a service. In the context of networks, a client refers to a communication process receiving information from others or getting connected to others by the means of transit services. A client process initiates service requests to others. But a pure client process is not able to serve requests from others, unless each participating device supports linked client and server processes. In contrast to a client process, a *server* refers to a process offering services. In networks, a server process hosts information for client processes to search, download, and so on.

The term *peer* means “equal,” which can be informally interpreted as a process with capability similar to the other processes with which process communicates. In the context of P2P networks, a peer process acts as a client process and at the same time as a server process for the same function. For example, a process that downloads files from others and meanwhile the process hosts shared files for others to download is a peer process in file downloading/uploading. There is no distinction between these processes in terms of which is providing or using services. Peer processes communicate with each other in a symmetric pattern. Note that the function that a peer process requests and offers must be the same within the context of a given application. A peer process can be

Figure 1: P2P and client/server models

instantiated variously as process, device (e.g., a network-connected computer or physical communication node), human being, etc.

Figure 1 illustrates the P2P and client/server models. In the client/server model, the server is involved in every file-uploading or downloading action. In the P2P model, peers bypass the server to transfer files among themselves. The dedicated server may still be present for some other functions, but it is unnecessary for every file to go through the server. The two models can coexist. Adding some server functions to the client and making it a peer do not eliminate the possibility of having dedicated servers for some functions.

There are several definitions of a P2P network. However, there is no well-accepted agreement about what is and what is not a P2P network. Collectively, these definitions of a P2P network give us an informal description of a P2P network, rather than a concise definition. Since P2P networks are rapidly evolving, it is healthy and desirable not to be restricted by a rigid definition, so that new technologies can be accommodated as they are introduced.

- A P2P network is the sharing of computing resources and services by direct exchange between systems (Milojicic et al. 2003).
- In a P2P network, computers at the edge provide power and those in the middle of the network are only for co-ordination (Milojicic et al. 2003).
- “P2P is a class of applications that takes advantage of resources—storage, cycles, content, human presence—available at the edges of the Internet. Because accessing these decentralized resources means operations in an environment of unstable connectivity and unpredictable IP addresses, P2P nodes must operate outside the DNS system and have significant or total autonomy from central servers” (Shirky 2000).
- A P2P network may be defined as an application layer overlay network in which all entities are equal and all contribute some of their resources, thus giving rise to a network in which each entity (peer) is both a content requestor and a content provider (Schollmeier 2001).
- “Peer-to-peer systems are distributed systems consisting of interconnected nodes able to self-organize into

network topologies with the purpose of sharing resources such as content, CPU cycles, storage and bandwidth, capable of adapting to failures and accommodating transient populations of nodes while maintaining acceptable connectivity and performance, without requiring the intermediation or support of a global centralized server or authority” (Androutsellis-Theotokis and Spinellis 2004).

- “A P2P system is one that has these five key characteristics: i) the network facilitates real-time transmission of data or messages between the peers; ii) peers can function as both clients and servers; iii) the primary content of the network is provided by the peers; iv) the network gives control and autonomy to the peers; and v) the network accommodates peers that are not always connected and that might not have permanent Internet Protocol (IP) addresses” (Miller 2001).
- A P2P network allows every computer in the network to act as a server to every other user on the network. A P2P network supports P2P applications in which computers share resources via direct exchanges between the participating computers (Barkai 2001).

Three criteria have generally been used to identify a P2P network: it should be self-organizing, have a symmetric connection, and have decentralized control (Roussopoulos et al. 2004; Milojicic et al. 2003). Peers organize themselves into a network in a collaborative manner. Peers are considered equals by requesting and offering similar services to each other. Peers communicate in a symmetric pattern, not being confined to either client or server roles. Peers share resources, while peers determine their level of participation and their actions autonomously. Generally, there is no central controller that dictates the behaviors of individual peers.

BENEFITS AND LIMITATIONS OF P2P NETWORKS

Benefits of P2P Networks

Cost Sharing and Reduction

The most significant benefit of a P2P network is cost sharing. To build a P2P network, no entity needs to commit

a large amount of resources or bear major network cost. The cost of the network infrastructure is naturally shared by participants. In a pure P2P network, every participant offers similar services to peers by contributing resources and sharing network cost. The network cost is spread to every participant, although the contribution of a participant may not be in proportion to the service that the participant receives from peers. In a hybrid P2P network, some nodes may be statically configured or dynamically assigned as supernodes offering additional services beyond that of ordinary participants. Such supernodes are mainly for bootstrapping, coordination, authentication, and so on. The major resource-consuming operations are still accomplished in a P2P manner. A well-designed P2P network should not overload the supernodes, and therefore the supernodes should not be a major cost.

A P2P network has a low entry cost for individual peers. In a centralized network, servers and the initial network infrastructure that a service provider builds bear a large percentage of the total cost, especially the initial capital expense; when such costs become too large, a P2P network helps spread the cost over all peers (Milojicic et al. 2003). This is important when no single entity has sufficient budget to build an initial centralized network, or when there is no clear business case for offering a service. In such a situation, a group of initial peers can build a P2P network by contributing their idle resources in trade for each other's additional services. A few P2P networks have evolved to millions of peers.

A fair cost sharing has always been an issue in P2P networks. Ideally, a peer trades idle resources for other resources that the peer requires to accomplish a task. Over time, the resources consumed by a peer should be in balance with the resources contributed by a peer. In reality, the lack of measurement of resource consumption and contribution may damage the faith of using a P2P network. In the extreme case, if a peer only enjoys "free services" offered by peers and does not contribute new services, then the "freerider" becomes a pure client of the network.

The cost reduction by a P2P network is a direct result of aggregating largely idle resources. A P2P network can offer services at a fraction of the cost of dedicated resources. A P2P network has a low entry cost for individual peers, although it may have a larger total cost (Roussopoulos et al. 2004). A P2P network offers an attractive alternative to a centralized network, when the initial budget is insufficient to build a service provider infrastructure using central servers.

Scalability

Different measurements of the scalability of a network or an application have been used. In Verma (2004), the scalability of an application was measured by the maximal user-level interactions that the application can support and still maintain reasonable performance. For example, the scalability of a Web server was measured by the number of user requests that it can support per second. The scalability of a directory server was measured by the maximal number of records that it can store and the maximal number of look-up operations that can be conducted within a given response time. In Mouftah and Ho

(2002), scalability was measured by the size of a network to accommodate a static traffic demand pattern.

A P2P network is scalable as long as an increase in the number of nodes also leads to a proportional increase in performance of the network. In a well-designed P2P network, the total network capacity can be smoothly increased as more peers join the network. The scalability of a P2P network is limited by a number of factors: the amount of centralized operations (e.g., synchronization and coordination) that needs to be performed, the amount of state that needs to be maintained, the inherent parallelism that an application exhibits, and the programming model that is adopted (Milojicic et al. 2003). A P2P network requires communication among peers to perform various tasks and thus has an overhead. For example, some file-sharing P2P networks rely on a central or distributed index or directory to locate the host computers of a given file. The search process is an overhead for the file downloading. If the overhead is not well controlled, the potential scalability of a P2P network may not be achieved. Both client/server and P2P networks have developed techniques to achieve excellent scalability (Verma 2004). For example, popular Web sites use scalable Web servers to handle millions of requests each day. Some P2P file-sharing networks support millions of file transfers each day. The difference is that a centralized network uses dedicated servers, whereas a P2P network uses existing idle resources in each user to achieve a scalable solution.

Resource Aggregation and Interoperability

A P2P network can use spare capacity distributed in existing systems. The resources can be storage capacity, computational power, communication bandwidth, information, and files. A P2P network uses end users' resources—i.e., the resource contributors are end users of the services. The end users pool their idle resources together to create new services, which would not be possible by acting alone. For example, enterprise file-sharing and collaborative software may be able to improve the way organizations share important documents, and organize the interactions of creating and editing documents (Dougherty 2001).

To aggregate diverse resources, interoperability is essential. *Interoperability* refers to the ability of any entity (device or application) to speak to, exchange data with, and be understood by any other entity (Schoder, Fischbach, and Schmitt 2004). The resources provided by peers typically have different attributes. P2P networks have been successfully implemented using heterogeneous resources, being independent of specific devices.

Improved Robustness

P2P networks are designed to cope with system and network failures, disconnections, and unreliable resources. Treating failures as normal is one of the fundamental design principles for P2P networks. Partial failures or disconnections of peers do not stop the function of an entire P2P network. In a robust P2P network, no single part of the network is essential to the operation of the entire network. Thus, even when a few peers are disconnected or defunct, the network remains functional.

Three terms are used to describe system robustness: reliability, availability, and survivability. In the strict sense, *reliability* is defined as the probability that a system successfully performs its designated functions at the designated performance level under stated conditions for a specified period of time. Reliability is about a failure-free operational period. In contrast, *availability* is the probability that a system is able to perform (i.e., not failed, not undergoing repair) its designated functions at the stated performance level. Availability is about how much time a system can be used. Availability can be measured as the total uptime out of the measured time. All corrective and preventive actions account for maintenance downtime instead of only failures. When a system has a long uptime, it is highly available. But this does not necessarily mean the system is highly reliable. An example is when the downtime of a system is very low, but the short system maintenance or failures happen very frequently. *Survivability* is a qualitative measurement. A system is considered to be survivable if it can maintain service continuity to the end users during the occurrence of any failure by using real-time protection mechanisms (Mouftah and Ho 2002).

A well-designed P2P network is very robust, thanks to its highly redundant resources, while maintaining low cost by not pursuing high reliability (in the strict sense). Individual building blocks in a P2P network are unreliable; they are up and down frequently. A P2P network's robustness may not be protected by any real-time mechanisms. Therefore, from an end user's perspective, a P2P network may not be highly reliable. However, restoration mechanisms improve the network availability. The restoration may need an end user's intervention or it may be conducted automatically. Although for P2P networks, availability is difficult to guarantee and high fault-tolerance is expensive, P2P networks enjoy massive availability of similar resources. For non-critical applications, P2P networks are a good compromise between availability and economics. For critical missions, application-layer recovery and restoration should be used to improve the availability.

Increased Autonomy

One of the design principles of a P2P network is that each peer autonomously determines when it joins or leaves a P2P network. Ideally, a P2P network should require no centralized management, oversight, or control. No central authority should force a peer to join a P2P network or cut off a peer's access to a P2P network. Each peer should be responsible for its own actions. Based on personal judgment and preference, the peer should decide the time to join or leave a P2P network, the resources it contributes to a P2P network, and the services it uses. Although a peer may have incentives to join a P2P network—e.g., contributing certain resources in exchange for certain services—the peer's participation should be voluntary. In reality, a P2P network may not achieve complete autonomy, and may still use centralized management for certain functions.

In a P2P network, each peer has two sets of policies that regulate how others use its resources and how it uses others' resources. The policies on using its own resources are mainly for safe sharing and protection purposes. The policies on using others' resources are mainly for preference,

discretion, and performance reasons. The policies include many aspects, such as when and to what extent a peer makes its resources available to other peers. The policies also depend on the characteristics of the resources and applications. For example, when a peer shares its CPU cycles, the peer may specify when others can use them, what percentage of the CPU cycles can be used by others, and which computational applications can use them.

Since each peer automatically sets up its own policies and cannot directly view or change others' policies, it is possible that different peers' policies may conflict with each other or may not respect the community's values. For example, in a file-sharing P2P network, a particular peer could have a policy specifying a preferred peer list, with which the file searching starts. If the peers at the top of the preferred peer list have a policy specifying not responding to the requests from this peer, then the performance that this peer perceives is negatively impacted. It would be advantageous if a peer's policies can be adjusted based on its past experience—e.g., removing nonresponding preferred peers after a certain number of failed trials. Real-time monitoring of resource usage and historical performance information are helpful for setting up policies.

In a P2P network, applications can be composed using components or modules distributed among different administrative domains. A centralized network is not a preferred architecture when the servers needed to host an application belong to different administrative domains. By using a P2P network, each administrative domain's autonomy is fully respected. A collaborative platform for multi-domain applications can be formed in a P2P network.

Anonymity and Privacy

A peer may prefer to be anonymous when participating in a P2P network, and may prefer to keep its communications with others private. The peer may want to protect its identity from being known to third parties, or even to its communicating partners. The peer may not want its communication activities to be monitored by third parties. In a centralized network, a server is typically able to identify a client (at least by the client's IP address), and the time and frequency of access by the client. In a P2P network, a peer may not want anyone, including a service provider, to know about its involvement—i.e., the peer may prefer to be anonymous. Three types of anonymity apply to a pair of communicating parties: sender anonymity, receiver anonymity and mutual anonymity (Pfitzmann and Waidner 1987). The spectrum of anonymity was identified in Reiter and Rubin (1998), ranging from complete anonymity (i.e., no third-party can perceive the existence of the communication) to no anonymity at all (i.e., a third-party can prove the existence of the communication, and identify the sender and receiver). Several interesting points exist in between, as shown in Figure 2.

Six techniques for improving a P2P network anonymity and privacy are summarized (Minami, Kamei, and Saito 2004): multicasting, faking a sender's address, faking identity, secret paths, intractable aliases, and nonvoluntary placement. Multicasting offers receiver anonymity. Faking a sender's address offers sender anonymity. Faking a sender's identity in the intermediate entities offers sender anonymity to the degree of possible innocence.

Figure 2: Degree of anonymity

A sender may protect his anonymity by using secret paths to a constantly changing middle party for store/forward. A receiver may protect her anonymity by using intrac-table aliases. A sender's anonymity can be protected by placement of the information in third parties without letting the third parties know it.

Privacy is information about identifiable peers. In P2P networks, privacy includes identity of peers, content, interests, location, etc. Privacy preservation in a P2P network tries to hide the association between the identity of a peer and the data that the peer is interested in. The platform for privacy preferences helps Web sites to express privacy policies while letting users automate users' acceptance or rejection decisions (Myles, Friday, and Davies 2003). Although such a platform is designed for Web sites, it can be tailored and applied to P2P networks. Such a platform does not attempt to enforce or ensure privacy through technology. Instead, social and legal pressures are relied on to compel organizations to comply with privacy policies.

Enhanced Dynamics

A P2P network offers a highly dynamic environment, where resources and peers enter and leave the network continuously. Compared to a centralized network that requires relatively stable servers, a P2P network is a natural fit for a highly dynamic environment. In traditional distributed networks, a node's disconnection is considered to be an exceptional event. However, a P2P network treats such an event as normal. A P2P network is built on a potentially large number of distributed resources that are contributed by autonomously operating peers. Thus, the inherent dynamics must be addressed by P2P network architectures. Each peer may participate in a P2P network temporarily, and leave the network without notifications to others.

P2P networks use special techniques to handle the transient nature of peers. Replication of critical resources is a widely used technique to deal with the dynamics of a P2P network. For example, files may be replicated in different peers to alleviate the impact of a peer's disconnection. To resolve the inconsistency in a reconnected peer, in Groove (www.groove.net) P2P networks, special nodes (called "relays") are used to temporarily store updates or communications, before the peer is reconnected. In Magi

(www.endeavors.com) P2P networks, messages may be queued at the sender until the receiver is presented. Techniques have been developed to deal with the dynamics of servers in a P2P network. For example, central servers can be bypassed during the communication between a sender and a receiver as soon as the sender and receiver are linked together. Therefore, even though central servers may be used in a P2P network, their use is a one-time action and is not restricted to any particular server among many redundant servers.

Ad hoc Communication and Collaboration

A P2P network can be formed in an ad hoc mode, by pre-configuration, or in a hybrid manner by combining both. The ad hoc communication in P2P networks is more of membership, rather than of the infrastructure. Peers participate in a P2P network in an ad hoc mode, joining and leaving the network as they want. Peers' participation is based on their own locations, interests, resource status, and other personal circumstances. A peer's participation in a P2P network has no long-term commitment and may be for a particular occasion only.

Self-organization techniques are used to manage a P2P network without a preexisting infrastructure. The highly dynamic peer joining and leaving in a P2P network increase the probability of failures, disconnections, and out-of-service events. Self-maintenance and self-repair of the network are required. Many P2P networks have no or little predefined configuration. Even the predefined configurations that are used in some P2P networks may change during the operation of the P2P networks. Adaptation is the key to deal with changes. It would be costly to have dedicated servers and/or network operators for managing a fluctuating P2P network. Thus, distributing management among peers is an efficient solution (Minami, Kamei, and Saito 2004).

Limitations of P2P Networks

Manageability

The deployment of a P2P network potentially running on different platforms is challenging. The deployment of a P2P network has a higher risk of running into undiscovered bugs in the infrastructure than in a centralized network. Debugging distributed software requires covering complicated interaction scenarios among many components. Compared to widely available development and testing tools for a centralized network, there are only a few development tools for P2P networks.

The maintenance of an operating P2P network is also difficult. Maintenance of a P2P network includes tasks such as ensuring the continuity of its operation, restarting it if necessary, making backup copies of the generated data, upgrading software, fixing software bugs, and educating users about the network operations and functions (Verma 2004). In a centralized network, by using a standard client software (e.g., a Web browser) or interface, there are few maintenance tasks for a client. Since servers are centralized and likely under the same administration, the maintenance of servers can be well planned and be conducted in a coordinated manner. Although a P2P network uses self-organization and self-maintenance

techniques to ease the difficulties of its maintenance, the manageability of a P2P network is not comparable to that of a centralized network. For example, upgrading the software of a P2P network is conducted on a voluntary basis and cannot be easily enforced. Another interesting example is that stopping a P2P network (as the last management task in its maintenance) cannot be easily accomplished due to its decentralization.

It is difficult to enforce standards in a P2P network. The operation of a P2P network needs certain common understanding and guidelines among peers. This common understanding covers technical aspects, as well as nontechnical aspects, such as social, moral, and ethical aspects. The recognition, adoption, and implementation of this common understanding are up to individual peers on a voluntary basis, as opposed to on a regulatory basis. The common understanding is in the form of recommendations, instead of standards.

The decentralized management in a P2P network results in no clear business model for a P2P network. To translate the operation of a P2P network into revenue flows, the P2P network needs management functions such as auditing, usage logging, authentication, authorization, and so on. These management requirements, to a certain extent, are contradictory to some benefits and design goals of a P2P network—e.g., anonymity and privacy. Until a successful business model of P2P networks is developed, P2P networks will operate mainly on a voluntary and amateur basis in the Internet, with virtually no technical support, or within an enterprise network where there are few requirements for a business model.

Security

A P2P network has very limited approaches to provide security against hackers, attacks, viruses, and other malicious damage. In general, the security of a centralized network can be managed much more readily than the security of a P2P network. A P2P network must apply security modules and mechanisms to many peers as opposed to a limited number of servers in a centralized network. The increased number of entities that need to be protected and the nature of multiple administration domains make the security in a P2P network even harder to solve.

Many security-management techniques rely on the proof of a party's identity. In these techniques, only after the identities of users, servers, or service providers are recognized and authenticated can further security management take actions such as granting a user access to certain information on a server, trusting the files downloaded from an accountable server, and exchanging encryption keys. However, in a P2P network, a receiver or a sender or both may want to be anonymous by hiding its identity. In addition, a peer may host files not created by the peer itself. The peer may not be aware of the contents and potential risk associated with the files. All these factors make verifying identity and contents very difficult in a P2P network.

Service Guarantee

The dynamic and transient nature of a P2P network makes it very difficult to guarantee the quality of service. In a P2P network, there is no service agreement or contract

in place to formally specify each party's responsibilities and commitments. Peers interact with largely unknown and changing partners and the potential number of partners is large and varying. Although informal community common understanding may be in place, the enforcement of such common rules is not ensured.

The robustness of a P2P network is based on the assumption of a large number of available redundant resources. Again, the availability of any resource is not guaranteed and is highly dependent on the type of resources, the time of use, and many other factors. The failure recovery may not be an automatic process and may require frequent human interventions. Thus, a peer's perspective and tolerance in a P2P network are dramatically different from those in a centralized network. An entire P2P network is fault-tolerant, which means that at least part of the network is operating in the event of partial failures. But, for an individual peer, ongoing communication may or may not be fault-tolerant, depending on the design of the network. So far, P2P networks are not used for critical missions that require stringent service guarantees.

Cheating and Selfish Behaviors

Selfish behaviors have been well observed in P2P networks. P2P networks operate based on the cooperation and contribution of individual peers. When there is little incentive for a peer to obey the rules, a peer may cheat and demonstrate selfish behaviors to maximize the peer's own utility of the network. For example, it has been shown that approximately 26% of Gnutella peers share no data; these peers participate in the P2P network only to download data and not to share (Saroiu, Gummadi, and Gribble 2002). In Napster (www.napster.com), they observed that on average 60 to 80% of peers contributed 80 to 100% of the shared files, implying that 20 to 40% of peers contributed few or no files. The peers who attempt to benefit from the resources of other peers and not offering resources in exchange are called "freeriders" of P2P networks. It has been documented that in 2000, approximately 70% of Gnutella (www.gnutella.com) peers provided no files and the top 1% of Gnutella peers contributed about 37% of the total files that were available in Gnutella (Feldman and Chuang 2005). In 2005, freeriders increased to 85% of all Gnutella peers.

Cheating behaviors in P2P networks usually appear as intentionally false reporting or configuration of system parameters. The vast majority of peers participate in P2P networks using third-party-produced software. Since typically there are system parameters representing a peer's capability or participation, the peer may cheat by manipulating these system parameters. For example, it has been reported that about 22% of Napster peers specified their bandwidth as "unknown." These peers either were unaware of their connection bandwidths or intentionally hid their true bandwidth (Saroiu, Gummadi, and Gribble 2002). Since knowing a peer's connection speed is more valuable to others than to the peer, a peer that reports high bandwidth is more likely to provide downloads to other peers, consuming network resources. It is advantageous to peers to falsely report their Internet connection speeds.

Incentive mechanisms are developed to counterattack the cheating and selfish behaviors in P2P networks (Feldman and Chuang 2005). Peers may offer resources in exchange for receiving other resources, under threat of retaliation, or out of generosity. Reputation mechanisms are useful in stimulating cooperative behaviors and providing accountability (Androutsellis-Theotokis and Spinellis 2004).

P2P NETWORK ARCHITECTURES

For most P2P applications, there are common requirements (technological and architectural), characteristics, and implications. Such a commonality is outlined in this section.

An abstract reference P2P network architecture consists of three layers: the base overlay layer, the middleware layer, and the application layer (Verma 2004). The layered architecture is shown in Figure 3. P2P networks have very diversified architectures. Some P2P networks are developed as single applications, possibly using proprietary implementations. Some P2P networks provide software modules that can be used to compose other applications. The three-layer reference P2P network architecture captures the major functional characteristics of P2P networks. However, it does not imply that a P2P network has to strictly follow the reference architecture.

Base Overlay Layer

The base overlay layer is responsible for ensuring that a peer is aware of the existence of other peers in a P2P network and is able to communicate with any other

peers. The base overlay layer is the foundation of a P2P network, which must be implemented in any P2P network architecture. This layer provides functions to discover other peers and then to create communication channels between them. The key functions in this layer include peer discovery, overlay network construction, and application-level multicast (Verma 2004).

Peer Discovery

The peer discovery enables a peer to be aware of the existence of all other peers in the same P2P network. Alternatively, a peer may discover a few other peers and with the help of these peers get to know more peers. Peer discovery needs to find out the identities of other peers—e.g., the IP addresses of other peers. A peer needs to discover the other peers' port number if the P2P network does not use a fixed port. Once the minimal set of properties to facilitate communication between peers is discovered, other properties about the peers can be obtained by communicating with the peers.

Static peer discovery can be used for a relatively static P2P network with a moderate number of peers. In static peer discovery, each peer is configured with a list of the IP address and/or the port number of all other peers in the network. A peer checks the availability of other peers at the start-up and periodically during its operation. Static peer discovery does not scale well and does not apply to very dynamic P2P networks.

Some P2P networks use a centralized index server to facilitate the discovery process—e.g., Napster (Sunaga et al. 2004). Although server-assisted discovery does not meet the principles of a P2P network, content exchange is performed on a P2P basis. Therefore, Napster is considered a hybrid P2P network. The discovery process in Napster includes steps 2 and 3 shown in Figure 4 (Loo 2003). It should be noted that in the Napster P2P network, the discovery process and the distributed search process are combined. When a peer discovers its peers, the peer searches for a target file at the same time. Generally, in a server-assisted peer discovery, since a peer does not need to know all the existing peers in the network, having some out-of-date registrations in the index server is not a significant problem. The drawback of an index server is that there is a single point of failure, which makes it vulnerable to attacks and shutdowns.

A peer in the Gnutella P2P network uses a discovery request and reply mechanism to discover new peers. Discovery of new peers on the network is critical for a system with a highly dynamic topology. A disconnected peer must have offline knowledge of at least one connected peer in order to connect to the Gnutella P2P network. The address of an existing connected peer can either be learned by searching available posted peers on the Internet or be set to a well-known peer such as gnutellahosts.com: 6346, which is almost always connected to the network. Once connected to the network, a peer is always actively involved in peer discovery. The Gnutella discovery request and reply mechanism is implemented by the Ping and Pong messages. A Ping message is a request for discovery of peers. A Pong message is used to send the discovered address of a peer to the requestor. The Gnutella discovery process is shown in Figure 5. All Gnutella messages

Figure 4: Operations of the Napster P2P network. The discovery process includes steps 2 and 3.

Figure 5: Gnutella discovery process

have a Time-To-Live (TTL) field that limits the message propagation range. A message ID field is used to uniquely identify each message so that a peer does not forward the same message more than once.

A gossip protocol randomly selects the peers to which a given message is forwarded (Portmann and Seneviratne 2002). Compared to the flooding technique, in which a message is forwarded to all peers except to the peer from which it was received, the gossip protocol is more scalable. Two additional parameters are specified: (1) the number of peers to which a message is forwarded, and (2) the times that a given peer forwards the same message. Since not all possible peers are forwarded to the first time, a peer needs to forward the same message more than once to find the remaining peers that the message has not been previously forwarded to.

In JXTA version 1.0, a peer announces its presence to the existing member peers by broadcasting within the

local area network (LAN), and Rendezvous Points (RPs) are used to relay announcements and discovery requests (i.e., queries) beyond the LAN boundary. Figure 6 shows the basic peer discovery mechanism in JXTA version 1.0. Additional peer discovery mechanisms include discovery through invitation and cascaded discovery. A peer may be invited to know another peer by receiving the remote peer's IP address. In a cascaded discovery, after the first peer discovers the second peer, the first peer may view the peers that have already been discovered by the second peer.

JXTA version 2.0 organizes RPs into a loosely coupled network (Traversat et al. 2003). A hierarchical discovery is used, in which RPs form the higher tier. Each RP maintains its own rendezvous peer view (i.e., an ordered list of other known RPs). When a peer joins the network, the peer uses a hash function to map its name, possibly together with other attributes to an RP. Then the obtained RP and its surrounding neighbors keep the index to this new peer. RPs relay peer discovery requests to the proper RP. If the proper RP is unavailable, a limited-range random walker approach is used to find redundant RPs. JXTA peer discovery can be used in highly dynamic environments, since JXTA does not require all peers maintain a consistent view of peers that are present in the network.

Overlay Network Construction

A P2P network constructs an overlay network on top of the existing network infrastructure. In a practical-scale P2P network, it is difficult to create a direct virtual link between every pair of peers. Therefore, a multiple-hop overlay network topology needs to be formed to carry control messages. A peer sends messages to a few neighbors in the overlay network and relies on those neighbors to forward them to other peers. The data traffic may need to be carried over the same overlay network as well. Alternatively,

Figure 6: JXTA discovery mechanism

a virtual link may be dynamically created between the pair of peers that need to transfer data traffic. The overlay network construction consists of two key technologies: virtual link creation and virtual topology control.

A virtual link is created to connect a pair of peers, making them direct neighbors in the overlay network. A virtual link in the overlay network is a logical connection on top of the basic transport layer. If no interfering devices exist on the physical path between the two peers that want to create a virtual link, the two peers need only to know each other's IP address and transport layer port number. Then, one peer initiates a connection request to the other peer who is waiting for incoming requests. A transport layer connection can be easily created. However, firewalls, network address translators (NATs), proxies, or other interfering devices may exist on the physical path. Most firewalls allow outbound connections, so that internal users can access the external Internet, at least for selected protocols such as the Web browsing protocol hypertext transfer protocol (HTTP). But internal users may not be allowed to listen to any incoming connection request. NATs are used for a number of users to share IP addresses. The users are configured to use the NAT as their gateway. At the NAT, TCP connections are modified to use one of the small number of NAT external IP addresses. Different TCP port numbers allow the NAT to dispatch return packets to correct users. From outside, the users behind a NAT appear to have the same IP address. HTTP proxies have the same effect. Creating a virtual link across such interfering devices needs special techniques. One such technique is tunneling through firewalls using the HTTP protocol. When two peers are behind two different firewalls, they need the help of an intermediary party outside of both firewalls to create tunnels across those firewalls. The intermediary party listens for incoming requests, usually by running a Web server on the Internet that both peers can access. The peers then exchange their messages through the intermediary party.

The virtual topology of an overlay network has a profound impact on the performance of the overlay network. Ideally, the diameter of the topology should be controlled under a certain bound, so that the largest distance (either by hop counts or by communication latency) between two peers is acceptable. In addition, each peer connects to a number of other peers, providing sufficient fault tolerance and not being overloaded by the interactions with too many neighbors.

Different overlay network topologies have been developed, which can be categorized as unstructured and structured overlay networks. In an unstructured overlay network topology, peers are added in an ad hoc manner, resulting in a random and nondeterministic topology. For example, each peer randomly connects to a few of the already-connected peers. A random overlay network works very well, when all the peers in a P2P network are roughly equivalent in terms of their connectivity and processing power. A hierarchical topology can be used for the overlay network, in which peers have very diversified connectivity and processing power. An example is a two-tier hierarchy in which core peers (also known as supernodes) are suitable for forwarding messages and edge peers are not. The core peers form a mesh topology and the edge peers connect to the core peers.

A structured overlay network topology is created based on specific rules. Therefore, the overlay topology is tightly controlled. Peers together with their content or shared files are placed at precisely specified locations in the overlay network. A structured overlay network essentially provides a mapping between peers and their physical location in the form of a distributed routing table. To define the mapping rules, many attributes can be used, such as the identifiers of the shared files that a peer hosts, etc. Each peer has a list of its direct neighbor peers in the overlay network—i.e., a distributed hash table (DHT).

To create an overlay network based on a DHT, four techniques are used:

1. Generating unique numeric keys for data, and giving unique identifiers to peers.
2. Storing keys in peers. Each key is stored in one or more peers whose identifiers are "close" to the key.
3. Building routing tables adaptively. Each peer maintains information (e.g., the IP address) of a small number of other peers in routing tables. As peers join, leave, or fail, the routing tables need to be updated.
4. Forwarding a look-up for a key to an appropriate peer. A look-up for a key yields the network location of a peer that currently is responsible for the given key. Any peer that receives a query for the key must be able to forward the query to a peer whose identifier is "closer" to the key. Eventually, the query arrives at the peer that holds the key (Figure 7).

Figure 7: A look-up forwarding process in an overlay network based on a DHT. The numeric portion (s) of a peer's identifier happens to be the same as the key (k) that is held by the peer. The distance between a peer's identifier and a key is defined as $(k - s + S) \bmod S$, where S is the total number of peers

A simple distributed file storage application based on a DHT can be built. Each file has a unique name, which can be converted into a numeric key using a hash function such as SHA-1 (secure hash algorithm 1). Then, the file is stored in the peers that are responsible for the key. A peer's file retrieval starts from a calculation of the key for the file. After that, the peer looks up for the key. If the peer does not host the file, the look-up is forwarded to an appropriate peer. The lookup forwarding continues until the peer that hosts the file is found.

Different overlay network topologies are used in different P2P networks—e.g., Chord (Stoica et al. 2001), Content Addressable Network (CAN) (Ratnasamy, Francis, et al. 2001), Pastry (Rowstron and Druschel 2001), Tapestry (Zhao et al. 2004), etc. Different overlay network topologies have different insertion overheads, measured by the number of messages for insertion when a peer joins a P2P network, different size of pointers to encode all peers and contents, and different maximum path lengths between two peers (Hildrum et al. 2002).

Chord defines a protocol to create overlay networks using a DHT (Stoica et al. 2001). It specifies how to find the locations of keys, how new peer nodes join the overlay network, and how to recover from failures or departures of peers. Each peer and key is assigned an m -bit numeric identifier. A peer's identifier can be derived by hashing the peer's IP address, while a key is generated by hashing the content, such as a filename, that is to be associated with the key. The identifier length m must be large enough so that it is very unlikely two peers (or two keys) are hashed to the same identifier. Identifiers are ordered in an "identifier circle" modulo 2^m . Key k is assigned to the first peer whose identifier is equal to or immediately after k on the identifier circle. Such a peer is called the successor of key k . Figure 8 shows the allocation of three keys to peer nodes in an overlay network.

To speed up the look-up process, Chord maintains additional routing information at each peer in the form of a "finger table." In the finger table of peer n , entry i ($1 \leq i \leq m$)

Figure 8: An example of three peers with identifiers 0, 1, and 3. Three keys—1, 2, and 6—are assigned to peers

points to the success of $n + 2i$. In this way, a finger table contains the IP addresses of peers halfway around the identifier circle from the peer, a quarter of the way, an eighth of the way, and so forth (Figure 9). A peer forwards a query for key k to the peer in the finger table with the highest identifier not exceeding k . Such look-up forwarding ensures that the look-up request can be forwarded at least halfway around the remaining identifier circle.

Chord provides a totally decentralized overlay network structure, in which no peer is more important than others. The storage of keys and processing of look-up requests are naturally balanced among peers. Chord can be used in very-large-scale overlay networks. In an N -peer overlay network, each peer maintains information about only a limited number of peers (i.e., $O(\log N)$ peers). Each look-up request can be processed after no more than $O(\log N)$ forwarding. A simple stabilization protocol is used to update the successor list and finger tables when peers join, leave, or fail.

Pastry is a mechanism to create tree-based, self-organizing overlay networks in the Internet (Rowstron and Druschel 2001; Castro et al. 2003). In Pastry, each peer node and key is assigned a numeric identifier with base 2^b , where b is a configuration parameter with a typical value of 4. A peer's routing table is organized into $\lceil \log_2 N \rceil$ rows with $2^b - 1$ entries in each row, where N is the total number of peers. In row n of the routing table, each entry refers to a node whose peer identifier matches the present peer's identifier in the first n digits, but whose $(n + 1)$ th digit is different from the present peer's identifier. In addition, each peer also maintains a leaf set—i.e., l number of peers among which half are closest larger identifiers and half are closest smaller identifiers compared to the present peer's identifier. l is an even integer parameter with a typical value of 16. The IP addresses of all peers in the routing table and leaf set are maintained. A look-up for a given key at the present peer starts from the present peer's leaf set. If the key is covered by the range of the leaf set, then the look-up is forwarded to the node in the leaf set whose identifier is closest to the key (possibly the present peer itself). If the key is not covered by the range of the leaf set, the look-up is forwarded to a peer that shares a common prefix with the key by at least one more digit. If no such closer peer

Figure 9: Finger tables and the resultant overlay topology of an overlay network with peer nodes 0, 1, and 3. (A) Finger tables, where $\text{finger}[k].\text{start} = (n + 2^{k-1}) \bmod 2^m$, $1 \leq k \leq m$; $\text{interval} = \text{finger}[k].\text{start}, \text{finger}[k+1].\text{start}$; $\text{successor}(k)$ is the next peer node on the identifier circle and $\text{successor}(k) \geq \text{finger}[k].\text{start}$. (B) The resultant overlay topology

exists, the look-up is forwarded to a peer that shares a prefix with the key at least as long as the present peer, but is numerically closer to the key than the present peer's identifier. Figure 10 shows the look-up-forwarding process in Pastry.

Pastry can efficiently handle look-ups and status updates in large-scale overlay networks. On average, a look-up from any peer can reach a target peer within $\lceil \log_2^b N \rceil$ steps. Even when multiple peers fail, a look-up can succeed unless $l/2$ or more peers with adjacent identifiers fail simultaneously. Each peer maintains only $(2^b - 1) * \lceil \log_2^b N \rceil + l$ other peer's IP addresses. After a peer failure or the arrival of a new peer, the relevant routing tables can be updated by exchanging $O(\log_2^b N)$ messages.

Figure 10: Forwarding a look-up from peer 78af51 for key d57af1 in Pastry. The dots indicate live peers in Pastry's namespace

CAN routes messages in a d -dimensional space, where each peer maintains a routing table with $O(d)$ entries (Ratnasamy, Francis, et al. 2001). On average, any peer can be reached in $(d/4)(N^{1/d})$ routing hops. The entries in a peer's routing table link to the peer's neighbours in the d -dimension space. When inserting a file into CAN, a set of keys are generated and mapped into diverse peers. In CAN, routing tables do not grow with the network size N . Only the number of routing hops grows (faster than $O(\log N)$, which is typical in other structured overlay networks).

Structured overlay networks (e.g., Chord, Pastry, CAN, etc.) are designed to support exact-match look-ups. The exact identifier (i.e., key) of a group of data must be known. Data are spread into peers with no consideration of data correlation. A comparison of different overlay networks is given in Milojevic et al. (2003), with respect to their models, parameters, hops to locate data, routing state, messages for a peer to join or leave, and reliability.

Application-Level Multicast

Multicast is the transmission of data to a group of receivers identified by a single destination address. In contrast, unicast is the transmission of data to a single receiver, and broadcast is the transmission of data to all possible receivers. The objective of multicast is to reduce the total amount of data traffic. Although IP layer multicast is available in some IP networks, few P2P networks use IP layer multicast for two reasons: (1) IP multicast cannot be used in conjunction with TCP, which is the transport layer protocol of choice in many P2P networks, and (2) IP multicast is not supported in every IP network. The key functions

Figure 11: IP-layer multicast versus application-level multicast

Figure 12: Different overlay network topologies lead to different total cost of the application-level multicast

to support multicast include group addressing mechanism, group maintenance, message-forwarding scheme, and multicast routing scheme. A group addressing mechanism provides a name or address as an alias for the members of a multicast group. Group maintenance supports members dynamically joining and leaving a group. When a message from a sender is forwarded to other group members, the message-forwarding scheme eliminates duplicate messages and avoids forwarding loops. The message-forwarding routes from a sender to all receivers in a multicast group is determined by a multicast routing scheme.

Application-level multicast offers a peer the capability of sending requests or announcements to a group of other peers in the same P2P network. Application-level multicast is the organization of peers in a point-to-multipoint (multicast) configuration—i.e., a delivery tree (Wierzbicki, Szezepaniak, and Buszka 2003). Application-level multicast in a P2P network can be achieved by broadcasting to a tailored overlay network, using a broadcast and filter approach to receive messages, or applying full-fledged multicast routing to an overlay network. Unlike IP layer multicast, in which data packets are replicated at routers inside the network, in application-level multicast, data packets are replicated at end hosts. Figure 11 illustrates the difference between IP-layer multicast and application-level multicast. The application-level multicast in Figure 11 does not rely on the IP-layer multicast function and is implemented on top of point-to-point IP packet delivery. However, application-level multicast incurs larger end-to-end delays than does IP multicast. Application-level multicast in a P2P network is provided over a reconfigurable overlay network topology. Thus, the integration of a multicast tree formation and an overlay network topology design may result in flexible networks and desirable performance. For example, an overlay network may be created by including only all the peers in a multicast group. The peers that want to join a multicast group can be added into the overlay network. Similarly, the peers that leave a multicast group can be withdrawn from the overlay network. By using the flooding-based broadcast

mechanism solely at end hosts, application-level multicast can be achieved without changing the network infrastructure or relying on IP-layer multicast.

To optimize the performance of an overlay network, traffic patterns and the underlying physical network topology need to be considered. Figure 12 shows that different overlay network topology leads to different total costs of the application-level multicast. Some overlay network topologies do not consider the proximity to the underlying physical network, so concentration and congestion points may be formed in the physical network. For example, in the overlay network topology 2 and 3, traffic is concentrated on the costly link between the two routers. In a CAN implementation, a peer may measure its network delay to a set of landmark nodes, so that the relative position of the peer in the Internet is estimated. Such information can be used to optimize the overlay network topology. Some overlay networks (e.g., Tapestry and Pastry) choose physically nearby peers as neighbors. A performance analysis of structured overlay networks can be found in Hildrum et al. (2002).

Scribe is an application-level multicast mechanism built on top of Pastry (Castro, Druschel, Kermarrec, and Rowstron 2002). Any peer node may create a multicast group; other peers can then join the group to receive multicast messages, or send multicast messages to all members of the group when the sending peers have appropriate credentials. Each group has a unique identifier that consists of the hash of the group's textual name and its creator's name. Scribe elects the Pastry peer node whose identifier is numerically closest to the group identifier as the topic rendezvous point and root of the multicast tree. Each Scribe multicast member is connected to the root via Pastry connections. The peer nodes that are in the middle of Pastry connections from the root peer to members are called "forwarders," which may or may not be members of the group. Each forwarder maintains a children table for a group. When a peer joins or leaves a multicast group, at each peer along the route to the root, the children table is updated. In the basic Scribe mechanism, multicast messages are delivered in a best-effort manner,

with no guarantee on delivery success and order. Additional guarantees can be built.

Narada uses a two-step approach to construct an application-level multicast (Chu et al. 2002). In the first step, a rich connectivity mesh is created for all group members. The path between any pair of members should have quality comparable to that of the underlying unicast path in terms of delay and bandwidth. To control the overhead of running routing algorithms on the mesh, each member should have only a limited number of neighbors in the mesh—not all members are neighbors to each other. However, Narada assumes that every member maintains a list of all other members in the group. Thus, Narada applies only to medium-sized groups. In the second step, Narada constructs spanning trees over the mesh topology obtained in the first step. Narada has advantages for several highly overlapped multicast groups. The overall group maintenance is reduced compared to maintaining individual multicast overlays.

Application-level multicast in CAN uses the routing tables maintained by CAN to flood messages to all peer nodes in a CAN overlay (Ratnasamy, Handley, et al. 2001). Therefore, no multicast tree is needed, and multicast traffic is not restricted to flow through a single multicast tree. When a peer joins a multicast group, the peer looks up a contact peer for the group in a global CAN overlay. Then the peer uses the contact peer to join the group's overlay. Only group members are involved in forwarding multicast messages in the CAN. The contact peer for the group is a performance bottleneck, since all members' join requests are handled by the contact peer.

In JXTA, application-level multicast is implemented the same way as JXTA peer discovery (Gong 2001; Traversat et al. 2003). Actually, JXTA multicasts a peer's announcement for the peer's presence and also multicasts a peer's request for discovery of other peers. Rendezvous points are used to facilitate multicast across the LAN multicast boundary.

The performance of the application-level multicast can be improved by adaptively changing the position of a peer in a multicast tree (Jannotti et al. 2000). Initially, a peer connects to the source peer itself. The source peer becomes the parent of the receiving peer in the multicast tree. Then, an iterative self-organization procedure is performed, in which the receiving peer tries to locate itself further away from the source peer. The bandwidth between the receiving peer and the current parent is

measured on a direct virtual link and on indirect virtual links through each of the parent's children. If the bandwidth to the source peer does not decrease significantly, one of the children is chosen to replace the parent. The procedure stops when no suitable replacement for the parent is found from all current children. The peer periodically evaluates its position in the multicast tree by measuring the bandwidth through other children of its parent, directly through its parent, and directly through its grandparent. The peer moves down or up in the multicast tree according to the measurements. In addition, the peer keeps a list of its ancestors, which is used for reconnection if its parent goes offline.

Middleware Layer

The middleware layer of a P2P network is the system software modules that reside between P2P applications and the underlying overlay network, providing reusable services that can be composed, configured, and deployed to create P2P applications rapidly and robustly (Blair, Campbell, and Schmidt 2004).

Distributed Search

Functionally, a distributed search includes several logical steps: from keywords to names, then to addresses, and finally to the paths to target destinations (Mischke and Stiller 2004). A peer specifies the keywords that describe the desired partner peers, contents, and resources. A keyword search returns the names or identifiers that satisfy the keyword description. Such names and identifiers must be unique in the network and can be in the format of a uniform resource locator/identifier (URL/URI), filenames in a networked file system, etc. In the look-up step, the unique names are mapped into addresses in the network—e.g., IP addresses. Finally, routing is the process of finding paths and forwarding search messages to the target destinations. To optimize the efficiency of distributed search, three shortcut techniques are used, as shown in Figure 13: keyword routing (i.e., semantic routing or content routing that takes advantage of P2P overlay network topology), keyword look-up, and name routing. These shortcuts combine two or more logical steps into one action.

Index mechanisms are at the heart of P2P distributed searches. An index is a collection of pointers to places where data can be found. Index mechanisms play an

Figure 13: Logical steps in a distributed search (Mischke and Stiller 2004)

important role in keyword searches, look-ups, and routing. The search/index links model is useful in understanding the relation and difference of P2P search and index (Cooper and Garcia-Molina 2005). Peers in P2P search and index networks form a partially connected overlay. In the search/index links model, there are two types of information links in this overlay network: search links and index links. Search links are used to forward queries between peers. Index links are used to send copies of content indexes between peers.

A P2P search process is an organized query-forwarding process. When a peer receives a query for given data, the peer attempts to answer the query as best it can. If this peer cannot answer the query, the query is forwarded to other peers, which also attempt to answer the query. Whenever a peer finds data matching the query, the location of the matching data is returned to the peer that initiated the search. The representation of the location of the matching data can be a peer node name, a peer node address, or a path to a peer node.

A P2P index assists the search process. A P2P index is an organized indexing information relay process. A peer may choose to send indexing information to a neighbor peer to improve the efficiency of P2P search. For example, assuming peer Y has received peer X's indexing information, when peer Y receives a query, peer Y can process the query based on both peer Y's own index and peer X's index copy. In this way, peer Y does not need to forward the query to peer X.

As an example, the search/index links model can be used to describe the operation of the Kazaa P2P search network (shown in Figure 14). The three peers in the middle of the figure represent supernodes in Kazaa. Other peers send their indexes to supernodes over index links. Queries are forwarded to supernodes over search links. Queries are processed at the supernodes and then forwarded to other supernodes if necessary. Since ordinary peers (i.e., non-supernodes) only handle the search or index that belongs to themselves, there are neither search links nor index links pointing to ordinary peers.

Fundamentally, a P2P search requires a series of mappings, from the keyword space to the name space, then to the address space, eventually to the space of paths to peer nodes (Mischke and Stiller 2004). The mapping process in a P2P search can be classified based on a tree structure, such as that shown in Figure 15. Further information on distributed index and directory is provided in the section on Other Middleware.

Figure 14: A representation of the Kazaa P2P search network using the search/index links model

Publish and Subscribe

Publish-subscribe is a middleware that supports sharing information among peers in a controlled manner. It provides the infrastructure on which the information-dissemination applications can be built. Publishers of information send messages (or events) to the publish-subscribe. Each message is associated with one or more subjects. In addition, each message may have a variety of attributes. Subscribers specify the subjects of the messages that they wish to receive. Subscribers may further specify under which conditions they are willing to receive the messages. Such conditions can be expressed in the format of equality tests and/or range values of the message attributes. Based on the flexibility and expressive power offered to subscribers to specify their interests, publish-subscribe can be categorized as subject-based (or topic-based) and content-based (or property-based). The content-based publish-subscribe may use brokers to match messages to interested subscribers. According to the decoupling of the communications between publishers and subscribers, publish-subscribe can be categorized along three dimensions: space, time, and synchronization decoupling (Eugster et al. 2003).

Although centralized publish-subscribe offers high throughput and reliability by using dedicated preconfigured servers, dynamically self-configured publish-subscribe is more attractive to large-scale P2P networks. The benefits and limitations of P2P networks that were discussed above generally apply to P2P publish-subscribe. In the P2P publish-subscribe, message producing, subscription, matching, and forwarding are distributed to peers.

P2P publish-subscribe can be implemented in two ways: broadcasting to all subscribers, or routing messages to subscriber groups possibly through brokers. In the first category, all messages are broadcast to all subscribers, regardless of subscribers' interests. Then, it is up to each subscriber to filter out the messages that are not of interest (Segall and Arnold 1997). Broadcasting to all subscribers is not efficient in a large P2P publish-subscribe. In the second category, a routing path for each message is created.

For subject-based publish-subscribe, application-level multicast is a readily available technique that can be used to send messages belonging to a specific subject to the subscribers along a multicast tree. Each subject needs a separate application-level multicast overlay. When a subscriber signs up for a subject, the subscriber joins the corresponding application-level multicast overlay. The publisher for a subject either becomes the root or sends messages to a proxy peer at the root of the corresponding application-level multicast tree (Castro, Druschel, Kermarrec, and Rowstron 2002; Zhuang et al. 2001). For content-based publish-subscribe, the key issues are the semantic expressiveness of content matching and the scalability of the matching mechanism. Brokers match the messages and identify the set of subscribers for the arrival messages. A peer node can be a publisher, a subscriber and a broker at the same time for different contents.

In content-based publish-subscribe, brokers are generally used to match and deliver messages. Siena and Gryphon allocate the responsibility of matching messages to a set

Figure 15: Classification of the mapping processes in a P2P search

of distributed broker servers (Carzaniga, Rosenblum, and Wolf 2001; Banavear et al. 1999). Messages follow a multicast tree to reach all matching subscribers. However, the self-organization capability of P2P networks is unavailable in Siena and Gryphon. Therefore, the broker servers require human intervention for set-up and management. In addition, Gryphon assumes that static subscription tables are maintained in all broker servers. Although messages are delivered only to related broker servers and eventually subscribers, subscription requests are flooded to all broker servers.

The event-distribution network (EDN) is a content-based publish-subscribe, built on top of a self-configuring overlay network of brokers (Wang et al. 2002). EDN partitions the content space into a set of disjointed partitions, and each partition is assigned to a broker. This approach minimizes message traffic by forwarding each message to only a single broker. However, subscriptions may need to be replicated to brokers. For equality tests, the attribute identifiers and values are hashed to generate a key to locate the broker managing the content partition. EDN

also partitions subscription filters and assigns the partitions to different brokers. However, messages may need to be forwarded to multiple brokers. EDN is limited to a fixed set of subscriptions, and its applicability to high-dimensional content space is unclear.

A content-based publish-subscribe can be built on top of a DHT (Tam, Azimi, and Jacobsen 2003). The set of attributes and their values are hashed to decide the brokers managing the subscriptions (shown in Figure 16). The content space is partitioned by hashing a set of selected attributes and their values into brokers, similar to EDN. For the range values of an attribute, labels are used to represent intervals, and labels are also hashed to locate brokers. The fault tolerance is provided by the underlying DHT. Since brokers match messages and subscriptions based on keys hashed from selected attributes and labels, false matches are possible and should be filtered out by subscribers themselves. In addition, subscribers may receive duplicate messages, because one single subscription may be hashed into multiple keys. The subscriptions and messages are limited by the preselected attribute sets (i.e., templates).

Figure 16: Hash messages and subscriptions to different brokers

Meghdoot uses CAN to build a content-based publish-subscribe (Gupta et al. 2004). Meghdoot imposes no restrictions on subscriptions or messages—i.e., no template is used. A subscription defines a rectangular region in the content space bounded by the minimal and maximal value specified. If the content space has D number of attributes, then a $2D$ -dimension CAN is constructed from the minimal and maximal values of the D -dimension rectangles. A subscription is projected to a point in the $2D$ -dimension CAN. A message is then mapped to a $2D$ space rectangle in which all relevant subscription points are covered.

A matching tree structure is used to organize subscriptions into hierarchical groups (C. Zhang et al. 2005). The matching tree supports multiple attribute types and allows customization of new attributes and filtering types. Messages can enter the publish-subscribe from any broker. A decentralized tree navigation algorithm is used to forward messages to tree fragments that may contain matching subscriptions.

Security

Security middleware for P2P networks is used to provide availability, privacy, confidentiality, integrity, and authentication. The attacks in P2P networks can be classified as attacks on services and attacks on data. Security middleware for P2P networks shares common security features of distributed systems, such as trust chains between peers and shared objects, session key exchange schemes, encryption, digital digests, and signatures. In addition, because of the open and autonomous nature of P2P networks, peers must be considered untrusted parties before authentications. Therefore, no assumptions can be made regarding a peer's behaviors.

In a P2P network, access keys for shared data may carry integrity verification information. When a peer inserts data into a P2P network, a cryptographic hash of the data is calculated and used to produce the data's unique access key. Since the hash function is known to all peers, when other peers retrieve the data using the unique access key, the data integrity can be verified by calculating a hash value of the retrieved data and comparing the hash value to the access key (Castro, Druschel, Ganesh, Rowstron, and Wallach 2002b).

Since P2P networks may rely on peers to forward requests and replies, a secure routing mechanism is used to prevent malicious peers from attempting to corrupt, delete, deny access to, or supply false copies of the requested data in P2P overlay networks (Castro, Druschel, Ganesh, Rowstron, and Wallach 2002). The secure routing mechanism consists of: (1) secure peer identifier assignment, (2) secure routing table maintenance, and (3) secure message forwarding. Secure peer identifier assignment uses a set of central and trusted certification authorities to prevent attackers from choosing identifiers. Without such a scheme, attackers may control all replicas of a given file or control all traffic to and from a victim peer. Secure routing-table maintenance ensures that faulty peers in routing tables do not exceed a certain percentage of total faulty peers in the entire P2P overlay network. Additional constrained routing tables are used when standard routing tables are compromised by attacks. Secure

message forwarding, from time to time, tests the routes used to forward messages. If a route fails, redundant routing is used. It has been realized that the techniques for secure routing introduce significant overhead.

The high redundancy and distribution of P2P networks can be used for security purposes. A technique for sharing secrets among peers is to encrypt data with a symmetric key K , then split K into l shares (Waldman, Rubin, and Cranor 2000). An algorithm is available to guarantee that any r of the l shares can reproduce K , but K cannot be reproduced by any $(r - 1)$ shares (Shamir 1979). The algorithm is based on polynomial interpolation: given r points in the two dimensional plane $(x_1, y_1), \dots, (x_r, y_r)$ with distinct x_i 's, there is one and only one polynomial $q(x)$ of degree $(r - 1)$ such that $q(x_i) = y_i$ for all i . But, the polynomial $q(x)$ cannot be reconstructed by using only $(r - 1)$ or fewer points. In the proposed mechanism, a peer hosts all of the encrypted data and one of the l shares. When a peer tries to retrieve the data, the peer randomly chooses r other peers that host the shares, and downloads the r shares. From one of the r peers, the encrypted data are downloaded. The encryption key is reconstructed by using the r shares. Then the encrypted data are decrypted using the reconstructed key. If any of the r shares or the encrypted data are altered, the decryption detects the alteration and consequently fails. It is the retrieving peer's responsibility to redownload the encrypted data from other peers or to choose different combinations of shares.

Providing security and anonymity at the same time is a challenge. A peer may prefer to anonymously publish, store, or request certain data. The secret sharing mechanism based on the distributed storage of a split encryption key, which is described in the previous paragraph, offers publisher anonymity (Waldman, Rubin, and Cranor 2000). Anonymous cryptographic relays are used to allow peers, which act as publishers, forwarders, storers, and requesters, to communicate anonymously (Serjantov, 2002). Through anonymous connections, encrypted blocks of data are sent from a publisher to selected forwarders and then from the forwarders to storers. Once all the blocks are stored, the publisher destroys the original data and blocks in itself. The publisher announces the data description and a list of forwarders. A requester for the data contacts the forwarders and then the storers. The requester repeats the process until all blocks are downloaded. In this way, the publisher's anonymity is protected.

Freenet provides an anonymous method for storing and retrieving information (Milojicic et al. 2003). Each file in the Freenet system is identified by a key generated using a hash function. Usually a short text description of the file is hashed to generate a key pair. The public key becomes the file identifier. The private key is used to sign the file for integrity check. The file's key is made available to users by Web sites or other mechanisms. Freenet participants pass and forward messages to find the location of an existing file or the proper location to store a new file. The keys are used to assist in the routing of these messages. Freenet is completely decentralized. When a user joins the Freenet, the user must use other methods to find at least one peer.

In P2P networks, reputation mechanisms are useful in stimulating cooperative behaviors and providing

accountability (Androutsellis-Theotokis and Spinellis 2004). Since strict measurement of individual peers' operation, performance, and availability may be difficult to apply in P2P networks, reputation is an alternative indicator. Reputation information is locally generated based on interactions between peers and is spread throughout the network to produce a global peer reputation rating. For example, global reputation values are computed from local reputation values assigned to a peer by other peers, weighted by the global reputation of the assigning peers. Another approach uses reputation computation agents, which are partially centralized. Then, the reputation values are encrypted and stored in such agents.

Other Middleware

Many generic functions in P2P networks can also be provided by middleware—e.g., distributed indexing, distributed directory, metadata, and scheduling. Distributed indexing can be used by applications such as a distributed storage application or a distributed file system. Distributed indexing middleware may use hash tables to map keywords of arbitrary length into a fixed-length hash value. Then the hash values are used to locate the entries corresponding to the keywords. A distributed directory middleware provides a name look-up service. A peer can look up the properties of an entity by specifying its name. Metadata middleware is used to describe the content stored in peers and may be queried to determine the location of desired information. Scheduling middleware is used in distributed computing or content-distribution applications. Computational tasks or contents are split into pieces and scheduled across peers.

Index middleware is used to store information about the location of data. In P2P networks, indexes need to be updated frequently, since peers join and leave the network constantly. Furthermore, the scalability of an index is critical, since an index may potentially be used for an Internet-scale network. A P2P index can be local, centralized, or distributed (Risson and Moors 2006). In a local index, a peer only maintains references to the peer's own data, and maintains no references to the data in other peers. Gnutella uses local indexes for each peer. Searches for data are flooded in the network. Actually, a search for data is equivalent to a search for the peers that host the data. The details of searches in Gnutella are described in the section on Peer Discovery. In a centralized index, a single server keeps references to data at all peers. Napster uses a centralized index. A centralized index is vulnerable to a single point of failure (or shutdown). The scalability issue of one single server for the entire network can be solved by linking multiple central servers. In a distributed index, pointers (direct or indirect) to data are stored in several peer indexes. The distribution of the indexes relies on the overlay networks. In a structured P2P overlay network, a peer maintains the index for the data assigned to the peer by the hash function. When searching for data, the hash value of the data is computed first. By using the hash value, the search is routed through the P2P overlay network to the peer that stores the data. When using unstructured P2P overlay networks for a distributed index, a peer may have one index summarizing the information of all peers on the path starting from this peer and within

a predefined distance. Such an index can also be arranged for each of the peer's links, summarizing the information of all peers on the path starting from a link and within a predefined distance.

Distributed directory provides a name look-up service. A peer can look up the properties (including location) of an entity by specifying its name. Together with distributed index, distributed directory assists the P2P search process. The mapping process in distributed directory generally uses distributed tables as shown in Figure 15.

Metadata middleware is used to provide interoperability for different data formats. Based on the schemes to represent data, P2P networks can be classified as three types: hash key-based, fixed schema or keyword-based, and schema-based. The former two types provide only domain-specific data formats. The last type intends to provide a unified scheme to represent data, which can be understood beyond specific domains. Metadata are machine-understandable structured information about Web resources, data, or other information resources. XML schemas are the standard metadata proposed by the World Wide Web Consortium (W3C). XML schemas express shared vocabularies and enable machines to carry out rules made by people. XML schema is a tool to define the structure, content and semantics of XML documents. The resource description framework (RDF) is based on attribute-value pairs to represent information on the Web. The Edutella project specifies and implements an RDF-based metadata infrastructure for P2P networks (Nejdl et al. 2002). Metadata operations are organized as: (1) query service—standardized query and retrieval of RDF metadata, (2) replication service—providing data persistence/availability and workload balancing to maintain data integrity and consistency, (3) mapping service—translating between different metadata vocabularies to enable interoperability between different peers, (4) mediation service—solving conflicting and overlapping information from different metadata sources, and (5) annotation service.

Scheduling middleware coordinates the execution time of the subtasks that are distributed to multiple peers. Computational subtasks are distributed and scheduled to peers in computational P2P networks. For content-distribution P2P networks, the subtasks can be at the stream or packet level. Pixie uses a scheduling middle-ware to coordinate multimedia streams (Rollins and Almeroth 2002). When a peer joins a P2P network and retrieves a content-distribution stream, the peer browses the schedule and chooses a scheduled distribution stream. Alternatively, the peer may request a new distribution stream to be scheduled. When a scheduled distribution stream starts, the source peer distributes the stream to all subscribed peers. Large-scale P2P live media streaming requires stringent playback quality, network scalability, and robustness to the high churn rate of peers and fluctuation of network conditions. Packet-level scheduling middleware is critical to meet such requirements (Zhang, Zhao, Tang, Luo, and Yang, 2005). GridMedia uses the scheduling middleware to fetch absent packets from a peer's neighbors and deliver packets requested by the neighbors. Each sending peer records the largest sequence number of the packets that are pushed to each neighbor. When a just-received packet

is far behind the packets that have been pushed to a neighbor, the new arrival packet is not relayed to the neighbor. Each receiving peer records the largest sequence number of the packets that are pushed from each neighbor. When a missing packet's sequence number falls behind the largest sequence number of the packets that are received from a neighbor by a threshold, the missing packet will be pulled from that neighbor. To cope with peer and network failures, when no packets have been pushed from a neighbor for a time-out period, all the packets that should have been pushed by this neighbor will be pulled from other neighbors.

Application Layer

P2P network applications can be classified into three categories: parallel computing, content and file management, and collaborative applications (Milojicic et al. 2003). Computationally intensive applications can be split into smaller pieces, which are executed in parallel over a large number of independent peers. In many cases, the same task is performed on each peer using different sets of parameters. P2P networks for content and file management use spare storage space and bandwidth. Different content- and file-management applications use different replication and search techniques. P2P file sharing and multimedia streaming are popular applications. Collaborative P2P networks allow peers to collaborate in real time, not relying on a centralized server to collect and forward information. Instant messaging, interactive gaming, Internet telephony and videoconferencing, and mobile ad hoc networking are examples of collaborative applications. More detailed discussions on P2P network applications are given in Chapter 145.

CONCLUSION

P2P networks are evolving technologies. Many exciting applications have been developed over the past few years. P2P networks have demonstrated their potential in many challenging environments and applications. The P2P network architecture will never completely replace other network architectures, such as the client/server architecture, but for particular applications, the P2P network architecture complements other network architectures.

The layered architecture of P2P networks abstracts the relations of different functions. However, different implementations of P2P networks may make design choices to use more efficient architectures. The reference P2P network architecture consists of three layers: the base overlay layer, the middleware layer, and the application layer. The base overlay layer provides peer discovery, overlay network construction, and application-level multicast. With the base overlay layer, P2P networks can be formed on top of existing physical networks by directly interacting between end users. The middleware layer offers distributed search, publish and subscribe, security, distributed indexing, distributed directory, metadata, and scheduling. The middleware layer provides some common functions that can be reused in different P2P networks. Although

we are still a long way from providing interoperability between different P2P network implementations, building common middleware is an effort in that direction.

Because P2P networks are evolving very quickly in very diversified directions, this chapter is by no means complete. As many people working in the area of P2P networks have pointed out, a P2P network is more of a mindset, rather than a specific technology.

GLOSSARY

Anonymity: A peer's anonymous participation in a P2P network, and preference of keeping its communication with others private. The peer may want to protect its identity from being known to third parties, or even to its communicating partners. The peer may not want its communication activities to be monitored by third parties.

Application Level Multicast: A function through which a peer is capable of sending requests or announcements to a group of other peers in the same P2P network. Application-level multicast is the organization of peers in a point-to-multipoint (multicast) configuration—i.e., a delivery tree.

Autonomy: Each peer's autonomous decisions regarding when it joins or leaves a P2P network. No central authority should force a peer to join a P2P network or cut off a peer's access to a P2P network. Each peer should be responsible for its own actions. Based on personal judgment and preference, the peer should decide the time to join or leave a P2P network, the resources it contributes to a P2P network, and the services it uses.

Client: A process using a service. In the context of networks, a client refers to a communication process receiving information from others or getting connected to others by the means of transit services. A client process initiates service requests to others.

Hash Function: A method of transforming data into a number. Hash functions provide a way of creating a small digital "fingerprint" from any kind of data. The function abstracts and mixes (i.e., substitutes or transposes) the data to create the fingerprint (i.e., a hash value).

Metadata: A structured description of an object or collection of objects. Metadata are information about a particular dataset, which may describe, for example, how, when, and by whom it was received, created, accessed, and/or modified and how it is formatted.

Middleware: Software that mediates between an applications program and a network. In P2P networks, middleware refers to the system software modules that reside between P2P applications and the underlying overlay network, providing reusable services that can be composed, configured, and deployed to create P2P applications rapidly and robustly.

Overlay Network: A virtual network built on top of another network. Nodes in an overlay network are connected by virtual or logical links, each of which corresponds to a path, perhaps through many physical links, in the underlying network. P2P networks are overlay networks because they run on top of the Internet.

Overlay networks can be classified as structured or unstructured.

Peer: An equal, which can be informally interpreted as a process with capability similar to the other processes with which this process communicates. In the context of peer-to-peer networks, a “peer” process acts as a client process and at the same time as a server process for the same function.

Peer Discovery: The process through which a peer knows the existence of other peers in the same P2P network. A peer may discover a few other peers and with the help of these peers get to know more peers. Peer discovery needs to find out the identities of other peers—e.g., the IP addresses of other peers. A peer needs to discover the other peers’ port number if the P2P network does not use a fixed port.

Peer-to-Peer (P2P) Network: A network in which resources and files are shared without centralized management. P2P networks are identified using three criteria: self-organizing, symmetric connection, and decentralized control. Peers organize themselves into a network in a collaborative manner. Peers are considered equals by requesting and offering similar services to each other. Peers communicate in a symmetric pattern, not being confined to either client or server roles. Peers share resources, while peers determine their level of participation and their actions autonomously. Generally, there is no central controller that dictates the behaviors of individual peers.

Publish and Subscribe: Middleware that supports sharing information among peers in a controlled manner. It provides the infrastructure on which the information-dissemination applications can be built. Publishers of information send messages (or events) to the publish-subscribe. Each message is associated with one or more subjects. In addition, each message may have a variety of attributes. Subscribers specify the subjects of the messages that they wish to receive. Subscribers may further specify under which conditions the subscribers are willing to receive the messages.

Rendezvous Point: A device that connects to more than one network, and is used to relay announcements, discovery requests, and queries beyond the broadcast boundary of a network.

Scalability: The ability to scale to support larger or smaller volumes of data and more or fewer users. It also refers to the ability to increase or decrease size or capability in cost-effective increments.

Server: A process offering services. In networks, a server process hosts information for client processes to search, download, and so on.

Structured Overlay Network: A type of overlay network, created based on specific rules. Peers together with their content or shared files are placed at precisely specified locations in the structured overlay networks.

Unstructured Overlay Network: A type of overlay network in which peers are added in an ad hoc manner, resulting in a random and nondeterministic topology.

INTRODUCTION

The term *peer-to-peer* appeared at the forefront of the public awareness around 1999, when the first version of Napster was released by Shawn Fanning. Since then, this term has been associated with illegal file sharing, copyright infringement, and lawsuits. Despite such a reputation, peer-to-peer (P2P) systems can be and are used in a very diverse range of application domains—to build virtual communities, to create reliable storage systems, and to solve large computational problems, to name a few.

Peer-to-peer systems are built around the concept of a “peer”—an individual computer providing its computational power, storage space, and bandwidth, and equipped with the corresponding software enabling it to join the P2P network. In a pure P2P system, there are no clients or servers—only peer computer nodes that do not require a centralized server to communicate with each other. Such P2P systems increase their performance, speed, and capacity as the number of peers increases. In contrast, in a typical client/server system with a fixed number of servers, adding more clients may result in a degraded system performance. The very concept of peer-to-peer eliminates a single point of failure because removing one or more peers from the network should not result in a diminished overall system performance caused by the replication of data stored among multiple peers and the redundancy of the network communication paths.

This chapter briefly surveys historical roots of P2P systems, from their origins to current and future developments, followed by a discussion of different application domains in which P2P systems are used today, in particular communication and collaboration, file sharing, distributed storage, and massively parallel computations. The chapter includes discussion of a wide variety of sample P2P network applications, illustrating their use in different application domains.

WHAT IS PEER-TO-PEER?

An examination of the current state of the art in peer-to-peer network applications requires establishing a criterion that would determine what a P2P system is. However, there is no clear consensus in the literature about a single definition of what “peer-to-peer” is. In the strictest sense, a pure P2P system is a distributed system in which nodes have completely equivalent functionality and range of tasks they can perform. This definition implies that each peer in the network acts both as a client and as a server in communication among the peers and that there is no central server responsible for managing the P2P network. Many existing P2P systems, however, do not fall into the category of a pure peer-to-peer system because most of them have one or more centralized servers, “supernodes” (in FastTrack network used by Kazaa, Grokster, and iMesh applications), or “ultrapeers” (in Gnutella network used by a wide range of P2P file-sharing applications) that are used for managing communication among the peers. A widely accepted but much broader definition of P2P systems (Shirky 2000) describes them as “a class of applications that takes advantage of resources—storage, cycles, content, human presence—available at the edges of the Internet.” Although this definition includes the true P2P systems mentioned above, it also covers many systems that rely on a central server, such as file-sharing systems (e.g., FastTrack and Overnet), a range of instant messaging systems, massively parallel computing systems (e.g., SETI@Home and Folding@Home), and Grid computing applications. This definition focuses not so much on the internal technical aspects of the system’s architecture, but rather on an external perception of a system that provides for a direct communication among peers.

To address the full range of P2P network applications, it is important to mention two characteristics of a distributed system that qualify it as a peer-to-peer system. First, a P2P system must enable peer computers to share

their resources with possible assistance from some kind of a centralized authority. Peers actively participate in the overall functioning of the network by performing tasks that are intrinsic to the operation of a P2P system, such as storing and locating content, routing communication messages, and locating, querying, and responding to requests from other peers, etc. Central server(s), if any, usually have a secondary role in the P2P system operation, such as assisting peers to join the network and helping them locate and establish a connection with other peers. However, central servers play a much more prominent role in some P2P network applications, in particular, in massively parallel computing systems described later in this chapter.

Second, P2P systems must be able to function effectively in conditions of varying network connectivity and constantly changing population of peers. A P2P system must be fault-tolerant and self-organizing by design, which requires having a network topology that will be adaptive to transient nodes and network connection failures (Androutsellis-Theotokis and Spinellis 2004).

HISTORICAL ROOTS OF P2P APPLICATIONS

Although the term *peer-to-peer* may be relatively new, the Internet itself was essentially conceived around the very same concept. In the 1960s, the main objective of ARPANET, the precursor to the Internet of today, was to effectively share computational resources scattered around the country. The underlying challenge was to enable communication among computers situated in the existing and future heterogeneous networks by introducing a sort of unified communication infrastructure among peer computers with equal rights (Minar and Hedlund 2001). Despite the fact that the early Internet was designed as a network of equal peers, the two original “killer apps” of the Internet, file transfer protocol (FTP) and Telnet, followed client/server architecture: a Telnet client could log on to a server computer, while an FTP client could upload files to or download files from a server. Despite this, the overall communication patterns in the early Internet

were symmetric, and any peer could act as a client and as a server. Furthermore, many network applications and services built years ago were based on the fundamental principles of P2P architecture; such examples including Usenet newsgroup server network, domain name system (DNS), and border gateway protocol (BGP) interdomain routing.

Usenet Server Network

Originally conceived in 1979—a decade prior to the World Wide Web, Usenet is a long-surviving fixture on the Internet scene that was designed to facilitate a discussion-based message exchange between users. The early version of Usenet was designed as a “poor man’s ARPANET” and built on top of UUCP (Unix to Unix copy protocol), which uses different types of physical and link-layer connections between two computers. In 1985, the network news transfer protocol (NNTP) was introduced to transmit Usenet traffic over TCP/IP. Although almost all of today’s Usenet traffic is transported over the Internet, most Usenet messages (called “articles”) still carry some UUCP-specific headers. The content of Usenet articles had evolved as well. Originally designed to carry exclusively text articles, the vast majority of the volume in Usenet traffic today is composed of binary files—images, MP3 files, videos, and software applications. Usenet articles are organized into newsgroups logically separated into hierarchically organized topics. For example, microsoft.public.xbox and microsoft.public.xbox.halo are two newsgroups within the microsoft.public hierarchy dedicated to Xbox and its Halo game, respectively. Figure 1 and Figure 2 show a part of the microsoft.public.xbox.* hierarchy displayed using the Xnews newsgroup reader and Google Groups. Usenet newsgroups are maintained and distributed over a network of NNTP servers. An NNTP server can join the Usenet network by establishing a connection with at least one other NNTP server, referred to as a newsfeed. The administrators of an NNTP server have control over which newsgroups their server carries and may decide how long different types of articles are to be retained. Today, newsgroups are flooded with sexually oriented and illegal content and therefore, some servers do not carry all of

Figure 1: Xnews, a newsgroup reader software, displays a partial list of the microsoft.public.xbox newsgroup hierarchy.

Figure 2: Google Groups can be used to access current and archived articles from virtually all Usenet newsgroups.

the available newsgroups. The alt.binaries.* newsgroup hierarchy carries almost exclusively this type of content; according to some sources, it is accountable for over 99% of all Usenet traffic volume.

A user can subscribe to a newsgroup carried by a given NNTP server, for example news.snet.sbcglobal.net. When the user posts an article to a newsgroup, initially it is available only on that server. However, during the communication with its newfeed(s), the new article propagates to other servers and eventually reaches all NNTP servers that are subscribed to the newsgroup to which that article was posted. Many modern P2P network applications function using a similar principle: a content item is copied from one peer to another peer that is interested in receiving it. In a typical P2P system, however, a given content item is not copied by all peers, but only by those peers that request that item. The principle of content replication in Usenet may seem inefficient given the existing network bandwidth capabilities, but it is inherited from the days when network connectivity was slow and not constantly available.

Usenet is completely decentralized both from the technical and from the organizational point of view. There is no central or coordinating server in the NNTP server network—instead, all NNTP servers have equal rights and differ mainly in the list of newsgroups they carry. The process of adding new newsgroups is controlled by a democratic voting process in a special news.admin newsgroup. Newsgroups in the alt.* hierarchy are an exception because they can be created by anybody at any time. Each NNTP server implements its own set of policies, yet the Usenet network as a whole functions through the cooperation of the entire community. Most existing P2P systems are either completely or partially decentralized using the same technical and organizational principles. A true P2P system operates without the need for a centralized server; most existing content-sharing P2P systems allow its users decide which content items are available to other peers on the network. There are, however, some

exceptions to these principles. For example, Freenet, a decentralized P2P data storage system aimed at fighting censorship (discussed later in this chapter), is designed to disallow any control over the content stored on the individual peer computers.

Domain Name System

Domain name system (DNS) is a vital component of the Internet because it provides functionality for associating hard-to-remember numeric IP addresses (such as 208.215.179.146) with easy-to-remember domain names (such as www.wiley.com). DNS was originally introduced in 1983 to support several thousand hosts, and it scaled extremely well to supporting hundreds of millions of hosts that exist today on the Internet. For a full description of DNS functionality, refer to Chapter 81 of this book. DNS has many features inherent to P2P systems. As DNS requests are propagated from one DNS host to the other, each host may act both as a client and as a server, which very closely resembles the peer concept in a P2P system. Caching replies to queries at each host helps the efficient scaling of DNS network. Any DNS host can query any other DNS host as may be necessary to resolve a given query, just like in P2P applications when a given peer can establish a connection with any other peer. Results of DNS queries are cached in each DNS host through which these result pass—P2P file sharing and distributed storage applications often use a similar method for replicating data.

P2P NETWORK APPLICATIONS FOR COMMUNICATION AND COLLABORATION

P2P systems are widely used for enabling direct and usually real-time communication and collaboration among peers. Early implementations of such systems include chat and instant messaging (IM) applications (ICQ [I seek

Figure 3: Psi is a Jabber-based IM client.

you] and a wide range of other systems developed by AOL, Yahoo, and MSN that copied the concept). These communication systems may be viewed as brokered P2P systems that are facilitated by one or more central servers used for managing an addressing system and for providing a unique identification for each peer. Other P2P communication and collaboration network applications that go far beyond basic instant messaging include Jabber, Skype, and Groove, which are discussed below.

Jabber

The Jabber project started in 1998 as a platform to enable interoperability among many incompatible IM applications and protocols (Miller 2001). With a first major release of software to the public in 2000, this project resulted in the development of XML-based open source extensible messaging and presence protocol (XMPP) used for instant messaging and managing presence information (which conveys a user's availability and willingness to engage in online communication). Today, according to Jabber Software Foundation (Jabber 2006), the Jabber platform and XMPP is used by over ten million people throughout the world.

The Jabber platform is decentralized and does not require a single central server, although a server is required to create an XMPP-based network. Jabber Software Foundation runs a public server at Jabber.org, and there are a large number of regional Jabber networks in many countries, each with its own server(s). In fact, any individual or a company can run a Jabber server to create his or her own public or private Jabber networks. An attractive feature of the Jabber platform is that all these networks are interoperable—that is, peers connected to different Jabber servers can still communicate with one another. In contrast, traditional IM platforms, such as MSN Messenger or AOL Instant Messenger are built around a central server and are not interoperable. Jabber allows its users not only to communicate with other peers on Jabber networks, but also with those connected to other popular IM systems through a number of specialized server-based

gateways, as if they were also on a Jabber network. The Jabber Web site provides a very long list of XMPP-based clients available for various operating systems that enable users to connect to Jabber platform; Figure 3 shows Psi, free Jabber-enabled IM client software.

A combination of the voice over IP (VoIP) and IM systems, Google Talk was introduced in August 2005. Google Talk uses XMPP to implement its IM functionality, but currently it does not support server-to-server communication. This implies that any Jabber client can connect to the Google Talk server, but it becomes limited to communication only with Jabber clients that are also connected to the same server, since Google Talk requires a special account based on a g-mail address. Google plans to eventually make Google Talk interoperable with other Jabber networks.

Skype

First released to the public in August 2003, Skype (2006) is a proprietary P2P VoIP network founded by Niklas Zennström and Janus Friis, the creators of Kazaa. Unlike many other VoIP systems, Skype usually works well over different types of network connections, including network address translation (NAT) and firewalls, which makes it especially attractive to home users. Calls within the Skype network are free; paid services include calling regular telephone numbers for a relatively low per-minute fee, and receiving calls from regular phones and using voicemail on a subscription basis. To join the Skype network, the user needs to download free Skype software, which is currently implemented for Windows, Mac OS X, Pocket PC, and Linux. A Windows-based Skype client is shown in Figure 4.

The Skype network uses P2P architecture by routing all calls through other Skype peers as well as distributing its user directory among the peers on the network. Skype peers connected without NAT usually see an increase in usage of their processor and network bandwidth as they are being used to route calls of other Skype users. In fact, in September 2005, Skype usage was essentially banned

Figure 4: Skype is a P2P VoIP network application.

in French public universities and research institutions, possibly due to excessive usage of the bandwidth capacities that are widely available at such organizations.

Skype code and protocols are closed source, and the company indicated that it has no plans of making them public. Skype effectively uses strong encryption to secure all aspects of its traffic, including session establishment and call data streams, all user log-ins are certified by a public key server, and its built-in file transfer capabilities are open to common antivirus tools.

The quality of voice calls made with Skype varies from excellent (better than traditional telephony) to almost unusable. Usual drawbacks include a time lag of about 0.5 second but sometimes up to 2 seconds due to low bandwidth and/or excessive P2P routing, and dropped calls.

Skype P2P architecture has proven to be able to scale up easily—Skype indicates that as of January 2006 their software has been downloaded over 230 million times, there are over 60 million users (about a half of them in Europe, a quarter in Asia, and about 10 percent in North America, according to statistics from Skype Journal (Skypejournal 2006), and there are over three million users concurrently using Skype network.

In September 2005, eBay acquired Skype for over \$2 billion. Many believe that such an astronomical amount is justified because this acquisition enables eBay to tap into the Skype user base, whose majority resides outside the current geographic pool of eBay's users, who are located mostly in North America. In late 2005, Skype 2.0 was released with a capability to make video calls to other Skype users as a major new feature.

Groove

Groove Networks was founded in 1997 by Ray Ozzie, the creator of Lotus Notes (Groove 2006). The company's product, Groove (currently marketed as Groove Virtual Office)

is a P2P groupware system; using this system, a team of collaborators (peers) may form ad hoc shared workspaces used to exchange messages, documents, applications, and relevant data—all related to a group project, as shown in Figure 5. Groove allows its peers to collaborate equally well regardless of the type or characteristics of their network connection: they can be behind a firewall or NAT; they can be on a corporate LAN, broadband connection, or dialup; and they can be always on or have an intermittent network connection.

Groove supports two key features that enable collaboration—security and synchronization. In effect, shared spaces created in Groove are instant virtual private networks. Groove requires each peer to have an account residing on a local computer. Groove's underlying philosophy stresses the idea that a peer can access their shared collaboration spaces from different computing or communication devices; therefore many identities may be associated with one peer account. At the same time, a single peer may have multiple identities that can be used in different shared workspaces. All messages exchanged by peers are authenticated and encrypted and usually do not contain entire documents. Groove uses "delta messages" representing incremental changes in a document, shared workspace, or its parameters—for example, a delta message could contain an individual keystroke. One of the objectives of Groove is to eliminate the human factor in enforcing strong security, since the vast majority of security failures are caused by a human oversight or error. Therefore, Groove provides strong security by default, offering very few security-related configuration options to its peers.

Groove's shared workspaces can be created by individual peers as well as by those working in the organizational frameworks of an enterprise. To support this, Groove offers a fully decentralized P2P communication mode and also provides means of incorporating enterprise-level

Figure 5: Groove Virtual Office is used to create a shared workspace containing files, discussions, group calendars, etc.

servers into its infrastructure (Groove 2005). In an enterprise environment, a range of servers is used by Groove: Enterprise Relay Server, supporting communication between Groove peers when a direct P2P communication cannot be established; Enterprise Data Bridge, providing integration between different workspaces and external systems' and Enterprise Management Server, supporting centralized control over licenses, security policies, and other administrative activities. Even if one or more of the central servers fail or if they do not exist at all, peers on a Groove network can still communicate and execute complex group tasks.

In March 2005 Groove Networks was acquired by Microsoft, and Ray Ozzie became one of Microsoft's three Chief Technical Officers.

P2P NETWORK APPLICATIONS FOR FILE SHARING

File-sharing applications brought P2P technology into the focus of public attention. The basic principle of file sharing is to copy a file from one computer to another using a direct network connection between the two computers. Gradually, P2P network applications took this concept to an entirely new level, from using Napster servers to help find computers with the right files to using swarm downloads in BitTorrent and ED2K (eDonkey2000) networks.

Despite frequent and numerous claims by the record industry that file sharing over P2P networks is the main cause of the decline in music sales, current research indicates that the real economic impact of file sharing is moderate at best (Oberholzer-Gee and Strumpf 2005). Although many sources disagree on the percentage figure, it remains a clear consensus that the vast majority of media distributed over P2P file sharing networks is copied illegally. However, there is a growing number of

legal uses of P2P file sharing networks: large volumes of open source software are distributed as compact disk (CD) images; unsigned music bands use P2P networks to publish their music; some gaming software publishers distribute updates to their products; and Peter Jackson's video documentaries on the making of "King Kong" were officially distributed via BitTorrent.

Napster

The original Napster was released by Shawn Fanning in June 1999. Specializing exclusively in MP3 music files, this service provided an easy method of locating computers with MP3 music files to those people who wanted to download them, as shown in Figure 6. Napster used only filenames to identify the content of each file, which often led to misrepresentation of the content being downloaded. At the time when Napster became vastly popular, the only ways to obtain an MP3 file was either to copy it from someone else or to rip it from a CD yourself; therefore, all file sharing activities conducted using Napster were considered illegal by major music recording companies, since no royalties were paid. Nevertheless, the use of Napster proliferated, reaching 50 million of registered users in January 2001 (Miller 2001), as users found many justifications for using the service. Many people wanted to have just one or two songs from otherwise worthless albums; others praised the service for allowing them to download songs that were difficult to obtain, such as old records and bootleg concert recordings.

Napster software allowed users to share their MP3 files with other Napster peers while providing capabilities to search for and download MP3 files from these peers. Napster servers maintained information about all peers connected to the network at any given moment and about the files these peers were sharing. To download a file, a Napster peer had to search the server for a

Figure 6: Napster was used to help locate computers with MP3 files available for download.

given artist and/or title (as represented by the name of the shared file) and then select a single peer that had this file from the list of results returned by the server. Once the peer with the needed MP3 file was identified, the two Napster peers established a direct connection and the file was copied. In fact, Napster architecture is very similar to that of most IM networks, which have central servers that maintain a list of active peers and help establish a direct connection between the peers.

Strong reliance on a central server made the Napster network not only technically vulnerable by creating a single point of failure, but it also enabled major copyright holders to mount a successful legal attack against Napster. Since Napster servers maintained a complete list of songs being traded, it was easy to prove in court that Napster as a company was aware of the copyright infringement. Despite numerous offers of settlement, Napster network was completely shut down in July 2001 to comply with court orders. Eventually, the Napster brand was acquired by Roxio Inc. at bankruptcy auction, which later launched a subscription-based music service, Napster 2.0.

Despite its flaws, Napster helped spark a widespread interest in and awareness of P2P network technology. It also helped create a new market for music services, which is currently dominated by Apple's iTunes. Most importantly, Napster's demise did not leave a void; instead it was quickly filled with other more advanced P2P systems used not only for file sharing, but also for many other purposes described later in this chapter.

Kazaa

Kazaa (Kazaa 2006) and its FastTrack protocol were introduced by Niklas Zennström and Janus Friis in

March 2001, several months before the complete shut-down of the Napster network. Similar to Napster, Kazaa Media Desktop (shown in Figure 7) and other FastTrack clients allowed users to join a P2P network to share files. Unlike Napster, the FastTrack protocol does not make any limitations on the types of shared files, allows downloading from multiple sources, and does not use a central server. The FastTrack protocol is proprietary and uses encryption for some parts of its functionality; however, some successful attempts have been made to reverse-engineer the unencrypted part of the FastTrack protocol.

If a powerful computer runs Kazaa or another FastTrack peer on a high-bandwidth connection, it usually automatically becomes a supernode on the FastTrack network. Each FastTrack peer has an updatable list of known supernodes, one of which is contacted when the client starts. Upon a successful contact, the client updates its list of currently active supernodes. The peer picks one of the supernodes as "upstream," through which all future search requests will be routed; it then uploads a list of shared files to its upstream. To facilitate downloading from multiple peers, unlike Napster, FastTrack does not use filenames to distinguish between different files. Instead, FastTrack uses the UUHash, a very fast, but unreliable hashing algorithm. UUHash uses a relatively small percentage of the file to produce its hash value, which allowed the Recording Industry Association of America (RIAA) and others to distribute fake and corrupt files on this P2P network (Oberholzer-Gee and Strumpf 2005). The most famous incident occurred in April 2003, when a number of full-length MP3 files with songs from the "American Life" album by Madonna appeared on the FastTrack network. These files started with less than a minute of the actual song material and then contained a recording of

Figure 7: Kazaa allows users to search the network for various media files.

Madonna asking the listener “What the [expletive] do you think you are doing?”

Soon after the release of Kazaa Media Desktop, its distributor company was sued in the Dutch court. As a result, Kazaa was sold to a complex network of offshore companies in the South Pacific, primarily to Sharmar Networks, based in Australia. Subsequently, Kazaa and manufacturers of other FastTrack-based software (Grokster) were sued by the RIAA, the MPAA (Motion Picture Association of America), the Australian Record Industry Association (ARIA), and MGM Studios. As a result of a long sequence of court rulings and appeals, many manufacturers of FastTrack applications have either closed, stopped distributing their software, or announced plans to establish new services that are free of copyright infringements. According to the Web site Slyck.com (Slyck 2006), the FastTrack network has been steadily losing ground since its peak in 2003, because of constant legal battles, including RIAA lawsuits against P2P users allegedly downloading copyrighted material, and simply because some FastTrack software plagues host computers with scores of malware. As of January 2006, Slyck.com data indicate that FastTrack has 1.9 million concurrent users on average.

Gnutella

Gnutella (Kan 2001) was developed by Justin Frankel and Tom Pepper, cofounders of Nullsoft and creators of the Winamp media player; it was released in March 2000, several months after Nullsoft was acquired by AOL. Gnutella client software was available on the AOL Web site for only one day, after which AOL removed the software from the Web site and prohibited Nullsoft from developing the project any further. Thus, the original Gnutella source code was never released, although its developers planned to do so. However, many copies of Gnutella software were downloaded; soon, the Gnutella protocol was reverse-engineered and made publicly available. Today, Gnutella is an evolving open protocol for P2P file sharing with a large number of existing peer software for Gnutella servers (*server* and *client*). Limewire, shown in Figure 8, is one of the most popular file-sharing applications using Gnutella.

Unlike the FastTrack protocol, which requires at least one supernode to form a network, Gnutella was originally designed as a protocol to build fully decentralized P2P file sharing networks of equal peers. In order to improve its scalability as the popularity of the protocol grew, Gnutella was later modified to include supernodes

Figure 8: Limewire is one of the most popular P2P file-sharing applications based on the Gnutella protocol.

referred to as ultrapeers responsible for managing search requests of other peers. To join the network, a Gnutella peer must find at least one other peer (neighbor) already connected to the network. There are many ways of finding such neighbors: some Gnutella software comes with a list of possibly working peers, there are Web sites with such lists, and finally, Internet relay chat (IRC) channels or word of mouth can be used to obtain the IP address of a working Gnutella peer. Once connected, a new Gnutella peer receives a list of other working nodes from its new neighbor, and in this fashion it can form a "neighborhood" of a certain number of peers it is connected to, up to a certain user-specified limit.

In the original Gnutella protocol, when a peer sends a search query, it floods the network with the search request: the peer sends the query to its neighbors; each neighbor passes it on to its neighbors, unless it can provide the specified file. If the peer with the sought file is not behind a firewall, it contacts the sender of the search request directly, and they negotiate the file transfer. Otherwise, the response is sent back along the route of the original request. If the requestor peer finds more than one peer with the sought file, it can download the file simultaneously from multiple peers, which increases the download speed.

In newer versions of the Gnutella protocol, search requests are routed among ultrapeers. However, searching the Gnutella network is not always fast or reliable. Since many Gnutella peers reside behind firewalls and/or have network connections with limited bandwidth (e.g., uplink bandwidth of most residential asymmetric digital subscriber line (ADSL) connections is several times less than the downlink bandwidth), and because many

peers do not stay connected to Gnutella network for a long time, most search requests reach far less than half of the network. At the same time, because of complete decentralization, the Gnutella network is extremely difficult to shut down—it will continue to exist as long as there are at least two peers. Slyck.com statistics (Slyck 2006) indicate that the population of the Gnutella network has been steadily growing, and it reached, on average, over 2.2 million daily users in January 2006.

eDonkey

The eDonkey2000 (ED2K) protocol was originally designed for the eDonkey2000 P2P file-sharing application developed and distributed by a New York-based company, MetaMachine. eDonkey2000 is a closed source software, and as of September 2005 it is no longer supported. Upon receiving a cease-and-desist letter from the RIAA, Sam Yagan, CEO of MetaMachine, said in his testimony at the U.S. Senate Judiciary Hearing on the future of P2P that MetaMachine is "in the process of complying with [RIAA's] request" and that his company intends to "convert eDonkey's user base to an online content retailer operating in a closed P2P environment." However, following these events, there was no change in the dynamics of the ED2K network population reported by Slyck.com—ED2K remains the most popular and steadily growing P2P file-sharing network, with a current average population of over 3.3 million concurrent users, as of January 2006 (Slyck 2006). One of the major reasons for the ever-growing popularity of ED2K network is the versatility of the open source protocol, allowing its peers to download multiple files from multiple peers simultaneously, and wide

Figure 9: eMule is the most popular software used to access ED2K file-sharing network.

availability of alternatives to eDonkey2000 also supporting the ED2K protocol; eMule, shown in Figure 9, is one of the more popular ED2K applications (eMule 2006).

The ED2K protocol is well suited for fast downloads of large files, such as full-length movies, software, games, and CD images. Files greater than 9.8 Mb are split into chunks, which can be shared with other peers before the entire file is downloaded. By doing this, ED2K forces the peer downloading the file to share it with others, which greatly enhances the availability of files in this network. Each ED2K peer maintains a queue of other peers wishing to download a chunk of a given file. To speed up the distributing of files across the network, each peer usually gets to download the chunk that the fewest other peers have. ED2K clients also have built-in mechanisms that help reward peers with high upload/download ratios, as they are given higher priority in the queue. Each file in the ED2K network is identified by an MD4 hash checksum computed for each chunk individually and then hashed once again to obtain the checksum for the entire file.

To join the network, an ED2K peer needs a server, which facilitates all network requests of a peer. At any given moment, an ED2K peer can find hundreds of running servers supported by volunteers. ED2K servers maintain a list of currently connected clients and checksums of the files they share; they also route search requests among each other. To overcome the dependency on the server, MetaMachine developed an alternative protocol—Overnet—that routes search requests among peers; the open source community of eMule developers created a

similar but incompatible protocol called Kademlia (usually referred to as Kad). It has been a trend to integrate at least two or more of the above protocols in a single client. For example, the latest available version of eDonkey2000 also supports BitTorrent (discussed later in this chapter) and allows a synchronized downloading of a file using BitTorrent, ED2K, and Overnet networks simultaneously. Together with the user-supported rating system, this helps eliminate fake and mislabeled files, which have become a significant problem for other P2P file-sharing networks, such as FastTrack.

According to data from Slyck.com (Slyck 2006), as of January 2006, among all P2P file sharing networks, ED2K was the most popular network, with over 3.5 million of concurrent users, on average.

BitTorrent

The concept of BitTorrent was developed by Bram Cohen, who released its first version in 2002. BitTorrent is an open protocol for a P2P file-sharing network; the same name is also used by the software, shown in Figure 10, developed by the protocol's inventor (BitTorrent 2006).

The overall functionality of BitTorrent protocol is similar to that of ED2K. Compared to ED2K, there are fewer files available to download on the BitTorrent network, but the download speeds are usually higher. However, unlike other P2P file-sharing networks, including ED2K, in which peers typically download multiple files at the same time, BitTorrent has been designed specifically to

Figure 10: BitTorrent software is used to download one file at a time.

download a single file from multiple peers at the same time. Similar to ED2K, files distributed in the BitTorrent network are downloaded in small segments (usually about 256 kB). A peer (referred to as seeder) that wishes to start distributing a file (a torrent) must create a special .torrent file that contains information about the shared file (its name, size, hash value of every segment) and the address of a tracker server responsible for coordinating the swarm (an ad hoc network of seeders and peers sharing the same torrent). The tracker server usually does not reside on the same computer as the seeder and is responsible only for updating the information about which torrent segments are available from which peers. Just like in the ED2K network, peers who have not completed downloading a torrent are forced to share the downloaded segments with other peers. Peers that complete the downloading of a torrent may opt to become seeders of that file. If all seeder peers of a given torrent are no longer online, even if there are peers that have its complete copy, new peers will not be able to start downloading that file. However, all peers that start downloading the torrent will eventually complete it, as long as there is at least one distributed copy of that file.

Unlike most P2P peer software, Cohen's BitTorrent peer program does not have a built-in search feature. To start downloading a file, a user of the BitTorrent network needs to locate a .torrent file. These are usually listed on specialized Web sites providing a search capability, sent by e-mail, or posted in corresponding Usenet newsgroups.

BitTorrent facilitates distribution of large amounts of data among a large number of peers in a relatively short time. Because of its features, among all P2P file-sharing networks, BitTorrent has been the most popular with pirates to distribute copyrighted material such as recent Hollywood movies. BitTorrent proponents argue that the network is not well suited for illegal file downloads: there are no good search facilities, seeder hosts of illegal files can be easily identified, and there are many ways that BitTorrent can be used for legal purposes—e.g. for distribution of large volumes of open source software. In fact, many BitTorrent search Web sites have been shut down under the threat of lawsuits or voluntarily. Despite a strong official antipiracy stance by Bram Cohen, in May 2005 he released a new version of BitTorrent that eliminates the need for tracker servers (thus making it much easier to distribute files) and updated the BitTorrent Web site to add a search feature that makes it much easier to locate both legal and illegal files.

Although it is more difficult to gauge the population of concurrent users of BitTorrent (Pouwelse et al. 2005), it is estimated that their numbers reached over 2 million in early 2006.

P2P NETWORK APPLICATIONS FOR DISTRIBUTED STORAGE

With the falling costs and growing capacity of hard drives, the primary concern of P2P network applications for distributed storage is not to gain additional space, but instead to store data in a distributed fashion to secure it against local failures and censorship. In the past, censorship-resistant P2P systems such as Freenet and Free Haven received a lot of publicity. According to the Web site of the Free Haven project, since 2002 it has been put on the back burner until some major implementation issues are resolved. Freenet is discussed below; this system is actively used by a relatively large community, although there is a controversy regarding the kinds of data available through this system. OceanStore, an academic project for reliable distributed document storage is also presented.

Freenet

The idea of what would eventually become Freenet was originally described by Ian Clarke in a paper written in 1999 and published a year later (Clarke et al. 2000). Clarke and a number of volunteers released the first version of this open source system in March 2000 (Freenet 2006). Since censorship may manifest itself by removing objectionable documents or punishing those who read, write, or distribute them, the primary objective of Freenet is to provide a censorship-resistant avenue for communication in an anonymous environment.

Freenet is a true P2P system, which has no central servers; therefore, it cannot be controlled by any individual entity. Peers in the Freenet network are responsible for secure storage of documents as well as processing and routing of document search queries from other peers. Each document available through Freenet is identified by a hash key, which is used in the key-based routing algorithm used by Freenet to locate documents. If the document exists, this algorithm finds the peer hosting the document that is the closest to the peer requesting the document. The distance between peers is measured in the number of peers that the request has to traverse.

Each peer on the Freenet network forms a small list of trusted neighbor peers. Each neighbor in the list is also assigned certain metrics that indicate the neighbor's past performance in retrieving documents based on different keys. Unlike Gnutella's network-flooding search algorithm, these metrics are used by Freenet peers to choose the neighbor through which a document search request is routed. A mechanism is in place to choose alternative neighbors to avoid loops in the search path. Each request also has a "hops to live" value that determines the maximum number of peers it can traverse before being terminated. A peer receiving a search request from its neighbor checks whether it has the sought document, and if so, it returns the document to that neighbor, which, in turn, forwards it to its original destination along the path of the request. To support anonymity, Freenet peers are not aware whether their neighbor requesting a document is the original requester or whether it has simply passed the request along. Peers may retain a copy of documents that pass through them, which makes the network more

resistant to censorship, as it makes it impossible to trace the origin of the document.

Freenet uses the same routing algorithm to insert new documents into its distributed data store. First, a search request is made for a document that does not exist yet. When the request fails, a new document is propagated along the same path as that search request, which ensures that the document is stored in the same peers that future search requests for that document will traverse.

The request routing algorithm and architecture of Freenet results in a situation in which popular documents are stored at more peers located closer to where requests for these documents are made. This makes it virtually impossible to remove a popular document from the network. Since all documents stored at Freenet peers are encrypted, users of the Freenet may not know what documents they are hosting on their computers. Freenet can be accessed using its Web-based interface, as shown in Figure 11.

Figure 11: Web-based interface to Freenet is provided by a background service running on the peer computer.

There is no easy way to determine what content is being actually stored on Freenet, since the network is designed to make such identification extremely difficult. Some estimates indicate that the majority of text information on Freenet is drug-related and the majority of all images are pornographic. Proponents of Freenet say that in order to maintain a true freedom of speech, one needs to be tolerable to the views of others, however questionable or unpleasant they may be.

OceanStore

OceanStore is an academic project led by John Kubiawicz from UC Berkeley (Kubiawicz 2003); as of January 2006 it was still largely under development, although a functioning prototype was available (OceanStore 2006). As with many P2P network applications for distributed storage, the main idea behind OceanStore is to replace storage on local hard disks with secure and redundant storage distributed across multiple computers spanning the entire Internet.

The objective of OceanStore is to provide highly available, consistent, and durable data storage utility built on top of an unreliable infrastructure of untrusted peers. OceanStore implements its objectives by replicating data over multiple storage locations, using decentralized object location and routing algorithms, and using strong cryptography. Documents inserted into OceanStore are split into multiple redundant segments, which are dispersed across the network. There are multiple copies of each segment stored in the network; even if some of these segments cannot be retrieved, the entire document can still be reconstructed. Developers of OceanStore claim that their system can scale well into millions of peers and that the documents inserted into the system will be kept there forever.

OceanStore is enabled by Tapestry, a P2P overlay network used for scalable, reliable, and location-independent message routing that provides decentralized object location and routing (DOLR) functionality. Tapestry makes use of locality in message routing while maximizing message throughput and minimizing message latency (Zhao et al. 2004). Tapestry belongs to the same class of overlay P2P networks as Chord (Stoica et al. 2001), Pastry (Rowstron and Druschel 2001), and CAN (Ratnasamy et al. 2001). These systems provide key-based routing (KBR) capabilities, supporting deterministic routing of messages to a network node associated with the destination key. These systems also support higher-level interfaces, such as decentralized object location and routing (DOLR) or distributed hash tables (DHT). DHT systems distribute the ownership of a set of keys among a number of participating nodes; they can efficiently route requests to the unique node that owns any given key. DHT systems are designed to scale well as the numbers of nodes grows and to be able to handle a large population of transient nodes that are prone to failures.

A distinguishing feature of Tapestry (and thus of OceanStore) is that it takes into account the network distance when constructing its routing overlay and thus attempts to minimize the physical span of a given overlay hop. Tapestry achieves this by constructing and maintaining

locally optimal routing tables. Unlike other DHT systems, Tapestry allows its applications to place content objects according to the application's needs. Tapestry makes location pointers available through its P2P network to enable efficient routing to the content objects with a minimal network stretch; as a result, queries for nearby objects are typically satisfied in the amount of time proportional to the physical network distance between the query source and the closest replica of the content object.

P2P NETWORK APPLICATIONS FOR MASSIVELY PARALLEL COMPUTING

The P2P approach is similar to grid computing architectures in that both use distributed processing by means of pooling together geographically dispersed and heterogeneous computing resources. Computational grids are primarily concerned with a coordinated distribution of computationally intensive tasks over a persistent and standardized service infrastructure. Designers of grid computing systems are also concerned with issues of scalability and fault tolerance, which will inevitably arise as computational grids grow to use an even larger number of processing nodes. Existing P2P systems are also concerned with the same issues, but their main focus lies in dealing with instability of a large population of transient peers. As mentioned earlier in this chapter, there is a growing trend among the developers of P2P network applications to build interoperable systems that share common protocols. As P2P systems continue to evolve and mature, one could expect a convergence of P2P and Grid approaches to build sophisticated network applications in the area of distributed computing, collaboration, and structured secure content distribution. These new architectures will address the issues of recovery from failures, scalability, and self-adaptation while operating in a standardized and persistent infrastructure. Today, however, "grid computing addresses infrastructure, but not yet failure, while peer-to-peer addresses failure, but not yet infrastructure" (Foster and Iamnitchi 2003).

One category of currently existing P2P network applications is sometimes classified as computational grids. Massively parallel computing systems make use of unused CPU cycles of geographically dispersed peers in order to solve a large computationally intensive task. A large computing task is broken down into relatively small units of work, which are distributed among the peers of such P2P systems. A common feature of these P2P systems is the presence of a central coordinating authority (a central server) responsible for breaking down and distributing the computational task among peers and collecting (and sometimes processing) of the results. Existing massively parallel computational systems include systems such as SETI@home (Korpela et al. 2001; SetiAtHome 2006) and the upcoming Stardust@home (StardustAtHome 2006) projects, both supported by the Space Science Laboratory at UC Berkeley; the currently terminated project Genome@Home (GenomeAtHome 2006) and the active Folding@Home (Folding-At-Home 2006; Larson et al. 2003) project, both supported by Vijay Pande of Stanford University, as well as other projects. Since many

Figure 12: BOINC-based software is used by SETI@Home project on a peer computer.

of the P2P network applications for massively parallel computations share the same architectural principles and feature one sample system, only SETI@Home is discussed below.

SETI@Home

SETI@Home was launched in May 1999. The main objective of SETI@Home (Search for Extraterrestrial Intelligence) is to analyze the radio-frequency data received from the Arecibo radio telescope in order to find evidence of intelligent radio transmissions from outer space. SETI@Home is said to be the largest distributed computing project, counting over five million participants throughout the world.

Over 25 GB of data per day from the Arecibo telescope is recorded on high-capacity tapes and shipped to Berkeley, where it is divided by time and frequency into 0.25-MB chunks of data distributed to individual peers of the SETI@Home network. Each peer runs a software client based on the BOINC (Berkeley Open Infrastructure for Network Computing) platform, as shown in Figure 12 (Anderson 2004). Data received from the central servers of SETI@Home are processed by peers that perform a variety of mathematical tests, mostly based on discrete Fourier transforms; upon completion of the analysis, the results are sent back to the central server. SETI@Home peers are run exclusively by volunteers, who often set up teams altruistically competing against each other for the

highest amount of work performed. SETI@Home peer software can run either as a screensaver or as a background task and is available for all major operating systems. According to the statistics provided by Boincstats.com (Boincstats 2006), as of January 2006, SETI@Home has the ability to compute over 200 TeraFLOPS while the combined computational power of all projects supported by the BOINC platform reaches over 300 TeraFLOPS.

CONCLUSION

P2P network applications have received a lot of media coverage and public attention in the recent years, primarily because of the legal implications of sharing copyrighted material. The concept of peer-to-peer architectures, however, had been used long before that; in fact, the earliest uses of P2P principles could be traced to the very roots of the Internet. Today, P2P network applications are successfully used in many areas, including file sharing, desktop collaboration, data storage, and distributed computing. Some view peer-to-peer as a disruptive technology, but it received such a label primarily because of the legal problems caused by P2P file-sharing applications. Although content traded on such networks remains largely pirated, they created a large and lively niche for legal media services providing consumers with a wide range of choices to purchase digital music and video content. Today, distributed computing systems based on P2P technologies reach

computing capacities that are comparable to that of the fastest supercomputers in the world (Top500 2006). According to the estimates of CacheLogic (CacheLogic 2006), 60 to 80% of the consumer ISP network traffic is caused by P2P network applications. P2P technology has been successfully applied in VoIP applications, instant messaging, and other consumer and business-oriented areas, not to mention a large number of academic projects exploring innovative uses of P2P architectures. Today, it is becoming obvious that peer-to-peer technology is here to stay.

GLOSSARY

Client/Server: An architecture for network applications that separates the client (e.g., user interface) from the server (e.g., database).

Extensible Messaging and Presence Protocol (XMPP): An XML streaming protocol, approved by the Internet Engineering Task Force for use in instant messaging and presence information.

File Sharing: A practice of making a file available for others to download.

Groupware: Software used to integrate the work on a single project by several individuals working at different computers.

Instant Messaging (IM): The process of instant communication between two or more people.

Malware: Derived from malicious software, which is designed to damage or cause harm to the computer or its user; refers to computer viruses, worms, Trojan horses, adware, spyware, etc.

Network Address Translation (NAT): Enables multiple hosts on a private network to access the Internet using a single public IP address.

Peer: A node in a peer-to-peer computer network acting both as a client and a server.

Replication: Provision of redundant service (e.g., storage) to improve a system's reliability and fault tolerance.

Single Point of Failure: In system design, refers to a part of the system, which, if it fails, will cause a significant interruption in the service provided by the system.

INTRODUCTION

Modern computing technologies have decentralized data-processing power in an unprecedented manner. An important implication is that user machines, be it a desktop computer or a handheld PDA (personal digital assistant), have data-processing power, in terms of instruction processing rate, amount of storage, and reliability, that was inconceivable merely a decade or two ago. Indeed, computing now occurs largely at the “edge” of networks. Network infrastructure systems have also made tremendous strides thanks to ever-improving communications technologies. Advancements in computing and communication, coupled together, enable a recent trend in a new form of distributed processing—peer-to-peer (P2P) computing (Roussopolos et al. 2004).

As its name implies, P2P computing involves users (or their machines) on equal footing—there is no designated server or client, at least in a persistent sense. Every participating user can be a server and a client, depending on context. Some people have referred to this as a “democratic computing environment” (Androutselli-Theotokis and Spinellis 2004) because users are free from centralized authorities’ control. This new paradigm of distributed computing has spawned many high-profile applications, most notably in file-sharing, such as: BitTorrent (Cohen 2003), Freenet (Clarke et al. 2000), Gnutella (<http://gnutella.wego.com>), and, of course, Napster (www.napster.com).

The highly flexible features of P2P computing, such as a dynamic population (users come and go asynchronously at will), dynamic topologies (it is impractical, if not impossible, to enforce a fixed communication structure), and anonymity, come at a significant cost—autonomy, by its very nature, is not always in harmony with tight cooperation. Consequently, inefficient cooperation or lack of cooperation could lead to undesirable effects in P2P computing. Among them, the most critical one is “free-riding” (Feldman and Chuang 2005) behavior. Loosely speaking, free-riding occurs when some users do not follow the presumed altruistic cooperation rules, such as sharing files voluntarily, sharing bandwidth voluntarily, or sharing energy voluntarily, so as to benefit the whole community.

Such altruistic sharing actions, presumably, would bring indirect and intangible (and even remote) returns to the users. For instance, if everyone shares files voluntarily, every user would eventually benefit from the high availability of a

large and diverse set of selections. Unfortunately, there are some users that do not believe or buy in to such utopia-like concepts and would, then, “rationally” choose to just enjoy the benefits derived from the community, but not contribute their own resources.

To deter or avoid free-riding behaviors, the P2P community has to provide some incentives—returns for resource expenditure that are, more often than not, tangible and immediate. Such incentives would then motivate an otherwise selfish user to rationally choose to cooperate because such cooperation would bring tangible and immediate benefits. To mention an analogy, in human society, getting pay for our work is a tangible and immediate incentive to motivate us to devote our energy, which could otherwise be spent on other activities. Indeed, it is important for the incentive to be tangible so that a user can perform a cost-benefit analysis—if benefit outweighs cost, the user would then take a cooperative action (Krishnana, Smith, and Telang 2003). It is also important for the incentive to be immediate (though this is a relative concept) because any resource is associated with an opportunity cost in that if immediate return cannot be obtained from a cooperative action, then the user might want to save the effort for some other private tasks.

To provide incentives in a P2P computing system, there are basically five different classes of techniques.

1. **Payment-Based Mechanisms:** Users taking cooperative actions (e.g., sharing their files voluntarily) would obtain payments in return. The payment may be real monetary units (in cash) or virtual (i.e., tokens that can be redeemed for other services). Thus, two important components are needed: (1) currency and (2) accounting and clearing mechanisms. Obviously, if the currency is in the form of real cash, there is a need for a centralized authority, in the form of an electronic bank, that is external to the P2P system. If the currency is in the form of virtual tokens, then it might be possible to have a peer-to-peer clearing mechanism. In both cases, the major objective is to avoid fraud at the expense of significant overhead. Proper pricing of cooperative actions is also important—overpriced actions would make the system economically inefficient while underpriced actions would not be able to entice cooperation.

2. **Auction-Based Mechanisms:** In some situations, in order to come up with optimal pricing, auctioning is an effective mechanism. In simple terms, auction involves bidding from the participating users so that the user with the highest bid gets the opportunity to serve (or to be served, depending on context). An important issue in auction-based systems is the valuation problem—at how much should a user set the bid? If every user sets a bid higher than its true cost in providing a service, then the recipient of the service would pay more than the service deserves. On the other hand, if the bids are too low, the service providers may suffer. Fortunately, in some form of auctions, proper mechanisms can be constructed to induce bidders to bid at their true costs.
3. **Exchange-Based Mechanisms:** Compared to payment-based and auction-based systems, exchange (or barter)-based techniques manifest as a purer P2P interaction. Specifically, in an exchange-based environment, a pair of users (or, sometimes, a circular list of users) serve each other in a rendezvous manner. That is, service is exchanged in a synchronous and stateless transaction. For example, a pair of users meet each other and exchange files. After the transaction, the two users can forget about each other in the sense that any future transaction between them is unaffected by the current transaction. This has an important advantage—very little overhead is involved. Most importantly, peers can interact with each other without the need for intervention or mediation by a centralized external entity (e.g., a bank). Furthermore, free-riding is impractical. Of course, the downside is that service discovery and peer selection (according to price and/or quality of service) could be difficult.
4. **Reciprocity-Based Mechanisms:** Whereas pure barter-based interactions are stateless, reciprocity generally refers to stateful and history-based interactions. Specifically, a peer A may serve another peer B at time t_1 and does not get an immediate return. However, the transaction is recorded in some history database (centralized in some external entity or distributed in both A and B). At a later time $t_2 > t_1$, peer B serves peer A, possibly because peer B selects peer A as the client because of the earlier favor from A. That is, because peer A has served peer B before, peer B would give a higher preference to serve peer A. A critical problem is how to tackle a special form of free-riding behavior, namely the “whitewashing” action (i.e., a user leaves the system and rejoins with a different identity), which enables the free-rider to forget about his or her obligations.
5. **Reputation-Based Mechanisms:** A reputation-based mechanism is a generalized form of reciprocity. Specifically, while a reciprocity record is induced by a pair of peers (or a circular list of more than two peers), a reputation system records a score for each peer based on the assessments made by many peers. Each service provider (or consumer, depending on the application) can then consult the reputation system in order to judge whether it is worthwhile or safe to provide service to a particular client. Reputation-based mechanisms are by nature globally accessible, and thus, peer selection can be done easily. However, the reputation scores

must be securely stored and computed, or otherwise, the scores cannot truly reflect the quality of peers. In some electronic marketplaces, such as eBay, the reputation scores are centrally administered. But such an arrangement would again need an external entity and some significant overhead. On the other hand, storing the scores in a distributed manner at the peer level would induce problems of fraud. Finally, similar to reciprocity-based mechanisms, whitewashing is a low-cost technique employed by selfish users to avoid being identified as a low-quality users, which would be excluded from the system.

The different techniques mentioned above are suitable for different applications. Generally speaking, there are two mainstream applications in P2P environments: sharing of discrete data and sharing of continuous data. Examples of the former include file-sharing systems (e.g., Napster) and data-sharing systems (e.g., sharing of financial or weather reports). A notable example of the latter is P2P video streaming. Indeed, there is an important difference between file-sharing and media-streaming systems. In the former, a user needs to wait until a file (or a discrete unit of shared information) is completely received before it can be consumed or used. Thus, there could be a significant delay between a service request and judgment of service quality. In an extreme case, a user may not discover that a shared file is indeed the one requested or just a garbage file until the file has been downloaded. By contrast, in a media-streaming application, a user would quickly discover whether the received information is good enough. The quality of service (QoS) metric used is also different in these two different applications. In a file-sharing application, the most important metrics are downloading time and the integrity of the received files. In a media-streaming application, the more crucial performance parameters are the various playback quality metrics such as jitter, frame-rate, and resolution. Furthermore, the incentive techniques surveyed in this chapter subsume the underlying P2P network topology. Specifically, in most proposed systems, the communication message-exchange mechanism is not explicitly modeled.

Currently, the majority of P2P systems are implemented over the Internet. However, wireless P2P systems are also proliferating. Although most of the incentive techniques designed for a wired environment could be applicable in a wireless system, the wireless connectivity is by itself an important bootstrap sharing problem. Indeed, on the Internet, users seldom pay attention to the connectivity issue because a user can be reached (or can reach) any other Internet user without noticeable effort. The only concern about communication is the uploading or downloading bandwidth consumption. In a wireless environment, however, the mere action of sending a request message from a client peer to a server peer would probably need several intermediate peers to help in the message forwarding because the server and client peers may be out of each other's transmission range. Consequently, incentives have to be provided to encourage such forwarding actions.

In this chapter, we survey state-of-the-art solutions proposed for tackling the incentive issues in various P2P resource-sharing systems. We describe approaches

designed for providing incentives in Internet-based P2P networks. We discuss both file-sharing and media-streaming applications. We describe solutions suggested for wireless P2P systems and then provide some of our interpretations and suggestions. At the end of the chapter, we summarize and provide some remarks.

INCENTIVE ISSUES IN P2P SYSTEMS ON THE INTERNET

File-Sharing Systems

In a file-sharing system, users would like to retrieve files from other users, and would expect other users to do the same from them. Thus, each user would need to expend two different forms of resource:

- **Storage:** Each user has to set aside some storage space to keep files that may be needed by other users, even though such files may not be useful to the user itself.
- **Bandwidth:** Each user has to devote some of its outbound bandwidth for uploading requested files to other users.

Users usually perform file selection (and hence, peer selection) with the help of some directory system, which may or may not be fully distributed. For example, in Napster (www.napster.com), the directory is centralized.

Using such a sharing model, the most obvious form of free-riding behavior is that a selfish user just keeps on retrieving files from others but refuses to share its collections (and thus, has no need to expend any outbound bandwidth for file uploading). Interestingly enough, in an empirical study using the Maze file-sharing system (<http://maze.pku.edu.cn>), Yang et al. (2005) found that the more direct indicator of free-riding behaviors is the online time of a user. Specifically, the online time of a selfish user in a P2P file-sharing network is on average only one-third that of a cooperative peer.

In this section, we first briefly overview a contemporary file-sharing system called BitTorrent (Cohen 2003). We then survey techniques suggested for various other P2P file-sharing networks.

BitTorrent

BitTorrent (Cohen 2003) is by far one of the most successful P2P file-sharing systems. A key feature in BitTorrent is that each shared file is divided into 256-kB pieces, which are usually stored in multiple different peers. Thus, for any peer in need of a shared file, parallel downloading can take place in that the requesting peer can use multiple TCP connections to obtain different pieces of the file from several distinct peers. This feature is highly effective because the uploading burden is shared among multiple peers and the network can scale to a large size. Closely related to this parallel downloading mechanism is the incentive component used in BitTorrent. Specifically, each uploading peer selects up to four requesting peers in making uploading connections. The selection priority is based on descending order of downloading rates from the requesting peers. That is, the uploading peer selects four requesting peers that have the highest downloading rates. Here, downloading rate refers to the data rate that

is used by a requesting peer in sending out pieces of some other file. Thus, the rationale of this scheme is to provide incentive for each participating peer to increase the data rate used in sending out file data (i.e., uploading, or, in BitTorrent's term, *unchoking*). There are other related mechanisms (e.g., optimistic unchoking), which are described in detail in Cohen (2003) and Qiu and Srikant (2004).

Qiu and Srikant (2004) performed an in-depth analysis of BitTorrent's incentive mechanism. By using an intricate and accurate model, it is shown that a Nash equilibrium exists in the upload/download game in BitTorrent. At the equilibrium, each peer sets its uploading data rate to be its physical maximum uploading rate (i.e., each peer is fully cooperative). On the other hand, because of the usage of the optimistic unchoking mechanism (a fifth requesting peer is randomly selected in the uploading process, for details, see Cohen [2003] and Qiu and Srikant [2004]), a free-rider can potentially achieve 20% of the possible maximum downloading rate. This theoretical result conforms nicely with the simulation findings by Jun and Ahamad (2005), who observed that in BitTorrent, free-riders are not penalized adequately and contributors are not rewarded sufficiently.

Hierarchical P2P Systems

In some situations, the P2P network may be structured in a hierarchical manner so that some specialized machines (called "superpeers") can take up a more important role for handling resource management tasks such as request forwarding and routing, directory listing, etc.

Singh et al. (2003) proposed a superpeer-based scheme. Specifically, they studied the impacts of superpeers in a P2P file-sharing network. Simply put, a superpeer is a special network node that serves as a hub to provide file indexing service to other nodes. The problem is the lack of incentive for a participating node to act as a superpeer, because any node can simply join an existing superpeer to obtain good performance. Singh et al. observed that some entities external to the P2P system, such as an Internet service provider (ISP) or a content publisher, have business-driven incentives for designating some nodes to act as superpeers, and for enhancing the capabilities of superpeers. Specifically, a superpeer can cache meta data only, instead of the files themselves. As such, the cost of acting as a superpeer is lower. Furthermore, with properly designed meta data, a superpeer can support value-added search commands (e.g., a topic-based search of files).

With such facilities incorporated in each superpeer, a hierarchical P2P file-sharing network is then much more efficient than a flat P2P system, which relies on request-flooding. Consequently, all nodes in the system have the incentive in maintaining such a P2P file-sharing system. Simulation results also indicate that the proposed superpeer scheme is effective.

Payment-Based Systems

Hausheer et al. (2003) suggested a token-based accounting system that is generic and can support different pricing schemes for charging peers in file sharing. The proposed system is depicted in Figure 1. The system mandates that each user has a permanent ID authenticated by

Figure 1: A superpeer-based token accounting system for P2P file sharing (based on Hausheer et al. 2003)

a certification authority. Each peer has a token account keeping track of the current amount of tokens, which are classified as local and foreign. A peer can spend its local tokens for accessing remote files. The file owner treats such tokens as foreign tokens, which cannot be spent but need to be exchanged with superpeers for new local tokens. Each token has a unique ID so that it cannot be spent multiple times.

At the beginning of each file-sharing transaction, the file consumer tells the file owner which tokens it intends to spend. The file owner then checks against file consumer's account kept at the file owner's machine. If the tokens specified are valid (i.e., they have not been spent before), then the file consumer can send the tokens in an unsigned manner to the file owner. Upon receipt of these unsigned tokens, the file owner provides the requested files to the file consumer. When the files are successfully received, the file consumer sends the signed version of the tokens to the file owner. In this manner, Hausheer et al. argued that there is no incentive for the peers to cheat.

Yang and Garcia-Molina (2003) proposed the PPay micropayment system, in which each peer can buy a coin from a broker. The peer then becomes the "owner" of the coin and can send it to some other peer. An important feature is that even after the coin is spent, the original owner still has the responsibility to check the subsequent use of the coin. For example, suppose A is the owner of a coin that is sent to B. If B wants to send the coin in turn to C, the original owner A needs to check whether such a transaction is valid (e.g., to avoid double spending of the same coin). If A is offline (e.g., temporarily departed the P2P system), then the broker is responsible for performing such checking.

Although the PPay system described above is a useful tool for supporting P2P sharing, Jia et al. (2005) observed that PPay can be further improved. Specifically, they proposed a new micropayment system, called CPay (an

improved version of PPay), which has one significant new feature—the broker judiciously selects the most appropriate peer to be the owner of a coin. Specifically, the owner of a coin should be one that is expected to stay in the system for a long time. Thus, the broker's potential burden of checking coin owners' transactions can be considerably reduced.

Figueiredo, Shapiro and Towsley (2005) also considered a payment-based system to entice cooperation among peers. Specifically, each peer requiring message-forwarding services from other peers needs to pay real money to these peers. Thus, as a peer stays in the P2P network and provides forwarding service to other peers, it can gain money. Indeed, such a monetary gain represents an incentive to enhance the availability of a peer in the network.

Saito (2003) proposed an Internet-based electronic currency called *i-WAT*, which can be used by users in a P2P system for "purchasing" services. Each *i-WAT* message is an electronic ticket signed using OpenPGP. Saito, Morino, and Murai (2005) then extended the *i-WAT* system by adding a new feature called "multiplication over time," which means that a requesting peer's debt (in terms of *i-WAT* units) increases over time. This feature then encourages service-providing peers to stay in the system for a longer time so as to defer the redemption of *i-WAT* tickets, thereby increasing the gains from the requesting peers.

Cost of Sharing

Varian (2003) reported a simple but insightful analytical study on disincentives in P2P sharing. Table 1 lists the notation used in Varian's analysis.

In Varian's model, a single item (e.g., a single music file) is considered and the system is homogeneous in that all peers have the same valuation on the item. There is an external central authority (e.g., the original producer of the music) that has the incentive to discourage sharing

Table 1: Notation Used in Varian's Analysis on Disincentives for P2P Sharing

Symbol	Definition
p	Unit price
v	Value of the item as perceived by each peer
n	Number of peers in the system
D	Total cost of producing all the items
$d = \frac{D}{n}$	Average development cost
k	Number of peers in each group that share an item
t	Sharing cost incurred by each member of a group
c	Cost imposed by the central authority to those peers who participate in sharing
π	Profit derived by the central authority

among peers in the system. The issue is then how the central authority can introduce proper disincentives into the system. First, observe that for viability in producing the item, we have:

$$v - \frac{p}{k} - t - c \geq 0 \quad (1)$$

$$p \frac{n}{k} \geq D \quad (2)$$

Specifically, the above equations are to ensure that value is no smaller than the cost.

The equilibrium (where the item is just viable to be produced) price and profit are then given by:

$$p = (v - t - c)k \quad (3)$$

$$\pi = (v - t - c)kn - D \quad (4)$$

We can see that profit is, counterintuitively, decreasing in c . An interpretation is that c is not large enough to discourage sharing and price has to be cut for compensation. As an analogy, consider that c represents some copy protection mechanism, which merely brings inconvenience to customers but cannot discourage sharing. To compensate for the inconvenience, the price has to be reduced.

On the other hand, for a given value of c , suppose the price is set in such a way that it is marginally unattractive to share. That is, we have:

$$\frac{p}{k} + t + c \geq p \quad (5)$$

This in turn implies that:

$$p = \frac{k}{k-1}(t+c) \quad (6)$$

Now, as the maximum practical value of p is v , we have:

$$c = v - \frac{k-1}{k}t \quad (7)$$

Yu and Singh (2003) also investigated the issue of proper pricing in the presence of free-riders in a P2P system. A referral-based system is considered, in that each peer can either answer a remote query directly (e.g., serving a requested file) or reply with a referral (e.g., pointing to a different peer who may be able to serve the requested file). A requester (i.e., file consumer) needs to pay for both a referral and a direct answer. Each peer keeps track of reserve prices of potential referrals and direct answers from any other peer. These reserve prices are updated dynamically based on transaction experiences in that a satisfactory transaction leads to an increase in the reserve prices while an unsatisfactory one leads to a decrease. From a seller's point of view, these prices are also exponentially decreased as time goes by. Under this model, simulation results indicate that a free-rider will quickly deplete its budget. On the other hand, the price of a direct answer is found to be much higher than that of a referral.

Courcoubetis and Weber (2006) have reported an in-depth analysis of the cost of sharing in a P2P system. In their study, a P2P sharing system is modeled as a community with an excludable public good. Furthermore, the public good is assumed to be nonrivalrous, meaning that a user's consumption of the public good does not decrease the value of the good. Such a model is suitable for a P2P file-sharing network, where the excludable public good is the availability of shared files. The model is also considered as suitable for a P2P wireless LAN environment, in which the excludable public good is the common wireless channel. With their detailed modeling and analysis, an important conclusion is derived: each peer only needs to pay a fixed contribution, in terms of service provisioning (e.g., a certain fixed number of distinct files to be shared by other peers), in order to make the system viable. Such a fixed contribution is to be computed by some external administrative authority (called a "social planner") by using the statistical distribution of the peers' valuations of the public good.

Reciprocity- and Reputation-Based Systems

Feldman, Lai et al. (2004) suggested an integrated incentive mechanism for effectively deterring (or penalizing) free-riders using a reciprocity-based approach.

Specifically, the proposed integrated mechanism has three core components: discriminating server selection, maximum-flow-based subjective reputation computation, and adaptive-stranger policies.

In the discriminating server selection component, each peer is assumed to have a private history of transactions with other peers. Thus, when a file-sharing request is initiated, the peer can select a server (i.e., a file owner) from the private history. However, in any practical P2P sharing network, we can expect a high turnover rate of participation. That is, a peer may be present in the system for only a short time. Thus, when a request needs to be served, such a departed peer would not be able to help if it is selected. To mitigate this problem, a shared history is to be implemented. That is, each peer is able to select a server from a list of global transactions (i.e., not just restricted to those involving the current requesting peer). A practical method of implementing shared history is to use a distributed hash table (DHT)-based overlay networking storage system (Stoica et al. 2001). Specifically, a DHT is an effective data structure to support fast look-up of data locations.

A problem in turn induced by the shared-history facility is that collusion among noncooperative users may take place. Specifically, the noncooperative users may give each other a high reputation value (e.g., possibly by reporting bogus prior transaction records). To tackle this problem, Feldman, Lai et al. (2004) suggested a graph theoretic technique. To illustrate, consider the reputation graph shown in Figure 2. Here, each node in the graph represents a peer (*C* denotes a colluder) and each directed edge represents the perceived reputation value (i.e., the reputation value of the node incident by the edge as perceived by the node originating the edge). We can see that the colluders give each other a high reputation value. On the other hand, a contributing peer (e.g., the top node) gives a reputation value of 0 to each colluder because the contributing peer does not have any prior successful transaction carried out with a colluder. With this graph, we can apply the maximum-flow algorithm to compute the reputation value of a destination peer as perceived by a source peer. For instance, peer B's (the destination) perceived reputation value with respect to peer A (the source) is 0 despite many colluders giving a high reputation value to B.

Finally, an adaptive-stranger policy is proposed to deal with whitewashing. Instead of always penalizing a

new user (which would discourage expansion of the P2P network), the proposed policy requires that each existing peer, before deciding whether to do a sharing transaction with a new user, computes a ratio of amount of services provided to amount of services consumed by a new user. If this ratio is great than or equal to 1, then the existing peer will work with the new user. On the other hand, if the ratio is smaller than 1, then the ratio is treated as a probability of working with this new user.

Sun and Garcia-Molina (2004) suggested an incentive system called Selfish Link-based InCentive (SLIC), which is based on pairwise reputation values. Specifically, any peer u maintains a reputation value $W(u, v)$ for each of its neighbor peer v , where the reputation value is normalized such that $0 \leq W(u, v) \leq 1$. Here, "neighbor" means a peer v currently having a logical connection with u and thus, such a peer v can potentially request service from u . With these reputation values, the peer u can then allocate the uploading bandwidth to any requesting neighbor peer v with a value of $W(u, v) / \sum_i W(u, i)$. The reputation value $W(u, v)$ is updated periodically based on an exponential averaging method.

Under this model, Sun and Garcia-Molina observed that each peer has the incentive to do some or all of the following, in order to increase its reputation values as perceived by other peers (and hence, enjoy a better quality of service):

- Share out more file data.
- Connect to more peers (to increase the opportunities for serving others).
- Increase its total uploading capacity.

Penalty-Based Approaches

Feldman, Papadimitriou et al. (2004) also investigated disincentive mechanisms that can discourage free-riding. Specifically, they considered various possible penalty schemes in deterring free-riders. A simple model is used. At the core of the model, each user i in the P2P sharing network is characterized by a positive real-valued *type* variable, denoted as t_i . Another key feature of the model is that the cost of contributing is equal to the reciprocal of the current percentage of contributors, which is denoted as x . Thus, for any rational user with type t_i , the user will choose to contribute if $1/x < t_i$ and free-ride if $1/x \geq t_i$.

Figure 2: A graph depicting the perceived reputation values among peers (*C* denotes a colluder) (based on Feldman, Lai et al. 2004)

Furthermore, the benefit each user derived from the P2P network is assumed to be of the form αx^β , where $\beta \leq 1$ and $\alpha > 0$. With this benefit function, the system performance is defined as the difference between the average benefit and the average contribution cost. Specifically, system performance is equal to: $\alpha x^\beta - 1$.

Even with the simplistic model described above, Feldman et al. provided several interesting conclusions. First, they found that excluding low-type users can improve system performance only if the average type is low and α is large enough. Unfortunately, exclusion is impractical because a user's type is private and thus, cannot be determined accurately by other peers. It is then assumed that free-riding behaviors are observable (i.e., free-riders can be identified). Such free-riders are then subject to a reduction in quality of service. Quantitatively, the benefit received by a free rider is reduced by a factor of $(1 - p)$, where $0 < p \leq 1$. A simple implementation of this penalty is to exclude a free-rider with a probability of p . The second interesting conclusion is that the penalty mechanism is effective in deterring free-riders when the penalty is higher than the contribution cost. In quantitative terms, the condition is that $p > 1/\alpha$. Finally, another interesting conclusion is that for a sufficiently heavy penalty, no social cost is incurred because every user will contribute (i.e., choose not to be a free-rider) so that optimal system performance is achieved. In particular, to deal with the whitewashing problem, the analysis suggests that every new user is imposed a fixed penalty. Essentially, this is similar to the case in the eBay system, where every new user has a zero reputation and thus, will less likely be selected by other users in commercial transactions. However, this is in sharp contrast to the adaptive-stranger policies suggested also by Feldman, Papadimitriou et al. (2004).

Game Theoretic Modeling

Ranganathan et al. (2003) proposed and evaluated three schemes induced by the Multi-Person Prisoner's Dilemma (MPD) (Osborne 2004; Schelling 1978). The basic Prisoner's Dilemma game models the situation in which two competitors are both better off when they cooperate than when they do not. However, without communication, the unfortunate stable state is that both competitors would choose not to cooperate. An MPD is a generalization of the basic PD. Specifically, the key features of the MPD framework can be briefly summarized as follows:

- The MPD game is symmetric in that each of n players has the same actions, payoffs, and preferences.
- Any player's payoff is higher if other players choose some particular actions (e.g., "quiet" instead of "fink").

The MPD framework is used for modeling P2P file sharing as follows. There are n users in the system, each of which has a distinct file that can be either shared or kept only to the owner. The system is homogeneous in that all files have the same size and same degree of popularity. Now, the potential benefit gained by each user is the access of other users' files. The cost involved is the bandwidth used for serving other users' requests. With this simple model, it can be shown that the system has a unique Nash equilibrium in which no user wants to share. Obviously,

this equilibrium is suboptimal (both at the individual level and at a systemwide level) in that each user could obtain a higher payoff (i.e., a higher value of net benefit) if all users choose to share their files.

Motivated by the MPD modeling, Ranganathan et al. proposed three incentive schemes:

- **Token Exchange:** This is a payment-based scheme because each file consumer has to give a token to the file owner in the sharing process. Each user is given the same number of tokens initially and each file has the same fixed price.
- **Peer-Approved:** This is a reputation-based scheme in that each user is associated with a rating that is computed using metrics such as the number of requests successfully served by the user. A user can download files from any owner who has a lower or the same rating. Thus, to gain access to more files in the system, a user has to actively provide service to other users so as to increase the rating.
- **Service Quality:** This is also a reputations-based scheme similar to peer-approved. The major difference is that a file owner provides differentiated service qualities to users with different ratings.

Theoretical analysis (Ranganathan et al. 2003) indicates that the peer-approved policy with a logarithmic benefit function (in terms of number of accessible files) can lead to the optimal equilibrium, in which every user contributes fully to the system. Simulation results also suggest that the peer-approved system generates performance (in terms of total number of files shared) comparable to that of token-exchange system, which entails a higher difficulty in practical implementation because it requires a payment system.

Becker and Clement (2004) also suggested an interesting analysis of the sharing behaviors using variants of the classical two player Prisoner's Dilemma. Specifically, the P2P file-sharing process is divided into three stages: introduction, growth, and settlement. In the introduction stage, the P2P network usually consists of just a few altruistic users who are eager to make the network viable. Thus, sharing of files is a trusted social norm. The payoffs of the two possible actions (supply files or not supply files) are depicted in Figure 3. Here, we have the payoffs ranking as: $R > T > S > P$ (Note: T = temptation, R = reward, S = sucker, P = punishment). Consequently, the Nash equilibrium profile is: (Supply, Supply). Notice that the payoffs ranking in the original Prisoner's Dilemma is: $T > R > P > S$, and as such, the Nash equilibrium is the action profile in the lower right corner of the table.

		Player 2	
		Supply g_2^1	No Supply g_2^2
Player 1	Supply g_1^1	R	T
	No Supply g_1^2	S	P

Figure 3: Payoff table in the introduction stage (based on Becker and Clement 2004) (g = strategy)

Player 1 \ Player 2		
	Supply g_2^1	No Supply g_2^2
Supply g_1^1	R R	S T
No Supply g_1^2	T S	P P

Figure 4: Payoff table in the settlement stage (based on Becker and Clement 2004)

In the growth stage, we can expect that more and more noncooperative users join the network. For these users, the payoff ranking becomes: $T > R > P > S$, which is the same as the original Prisoner's Dilemma. Thus, the Nash equilibrium for such users occurs at the profile: (No Supply, No Supply). As the P2P network progresses to the mature stage (i.e., the size of the network becomes stabilized), we can expect that a majority of users are neither fully altruistic nor fully noncooperative. For these users, the payoff ranking is: $R > T > P > S$. As a result, the payoff matrix is as depicted in Figure 4. As can be seen, there are two equally probable Nash equilibria: (Supply, Supply) and (No Supply, No Supply). Consequently, whether the P2P network is viable or efficient depends on the relative proportions of users in these two equilibria. Results obtained in empirical studies (Becker and Clement 2004) using real P2P networks conform quite well to the simple analysis described above.

Ma et al. (*A Game Theoretic Approach*, 2004; *An Incentive Mechanism*, 2004) suggested an analytically sound incentive mechanism based on a fair bandwidth allocation algorithm. Indeed, the key idea is to model the P2P sharing as a bandwidth allocation problem. Specifically, the model is shown in Figure 5. Here, multiple file-requesting peers compete for uploading bandwidth of a source peer. Each requesting peer i sends a bidding message b_i to the source peer N_s . The source peer then divides its total uploading bandwidth W_s into portions of x_i for the peers. However, because of network problems such as congestion, each peer i may receive an actual uploading bandwidth of x'_i which is smaller than x_i .

Each bidding message b_i is the requested amount of bandwidth. Thus, we have $x_i \leq b_i$. To achieve a fair allocation, the source peer uses the contribution level C_i of each competing peer i to determine an appropriate value

Figure 5: Two file-requesting peers (N_1 and N_2) compete for uploading bandwidth of a source peer (N_s) (based on Ma et al., *A Game Theoretic Approach*, 2004)

of x_i . Ma et al. (*A Game Theoretic Approach*, 2004; *An Incentive Mechanism*, 2004) described several allocation algorithms with different complexities and considerations: simplistic equal sharing, maximum-minimum fair allocation, incentive-based maximum-minimum fair allocation, utility based maximum-minimum fair allocation, and incentive with utility-based maximum-minimum fair allocation. The last algorithm is the most comprehensive and effective. It works by solving the following optimization problem:

$$\max \sum_{i=1}^N C_i \log \left(\frac{x_i}{b_i} + 1 \right) \quad (8)$$

where:

$$\sum_{i=1}^N x_i \leq W_s \quad (9)$$

Here, the logarithmic function represents the utility as perceived by each peer i .

The above optimization problem can be solved by a progressive filling algorithm that prioritizes competing peers in descending order of the marginal utility $C_i/(b_i + x_i)$.

Given values of b_i and C_i , the source peer can compute the allocations in a deterministic manner. However, from the perspective of a requesting peer, a problem remains as to how it should set its bidding value b_i . Using a game theoretic analysis, it is shown that the action profile in which:

$$b_i = \frac{W_s C_i}{\sum_{j=1}^N C_j} \quad \forall i$$

is a Nash equilibrium. Furthermore, provided that all cooperative peers use their respective strategies as specified in the Nash equilibrium action profile, collusion among noncooperative peers can be eliminated. Notice that each requesting peer i needs to know the values of W_s and $\sum_{j=1}^N C_j$ in order to determine its own bid b_i . In a practical situation, these two values can be supplied by the source peer to every requesting peer.

Auction-Based Approaches

Gupta and Somani (2004) proposed an auction-based pricing mechanism for P2P file object look-up services. In their model, each resource (e.g., a file object) is stored in a single node. However, the indices for such a file object are replicated at multiple nodes in the network and these nodes are called "terminal nodes." When a peer initiates a look-up request for a certain file object, the request is sent through multiple paths toward the terminal nodes, as shown in Figure 6. The problem here is that the intermediate nodes need some incentives in order to participate in the request forwarding process.

Gupta and Somani (2004) suggested a novel solution to the incentive problem. Specifically, the initiating peer attaches a price in the request message it sends to the first layer of nodes in the request chains. Each intermediate node on the request chains then updates the price by adding its own "forwarding cost." The terminal nodes do the

Figure 6: The request-forwarding process (based on Gupta and Somani 2004)

same updating before sending the request messages to the data source. Upon receiving all the request messages, the data source then performs a second price sealed bid auction (also referred to as Vickrey auction) (Osborne 2004) to select the highest bid among the terminal nodes. The selected terminal node then needs to pay the price equal to the value of the second-highest bid. With this auction-based approach, all the intermediate nodes on the request chains have the incentive to participate in the forwarding process because they might eventually get paid by the requester should their respective request chain wins the auction.

For example, consider the look-up process shown in Figure 7. We can see that the request chain terminated by node T1 wins the auction process and the payoff to the data source node B is 60. The only intermediate node (node 1) then also gets a payoff. Gupta and Somani (2004) also showed that a truthful valuation in is the optimal strategy for each intermediate node. Furthermore, based on the requirement that every message cannot be repudiated, it is also shown that the proposed mechanism can handle various potential threats such as malicious auctioneer, collusion between data source and a terminal node, forwarding of bogus request message, etc.

Wongrujira and Seneviratne (2005) proposed a similar auction-based charging scheme for forwarding nodes on a path from a requesting peer to a data source. However, they pointed out an important observation that some potential malicious peers could try to reduce the profits of other truthful peers by dropping the price messages.

To mitigate this problem, a reputation system is introduced in that every peer maintains a history of interactions with other peers. The reputation value of a peer is increased every time a message is forwarded by such a peer. On the other hand, if an expected message exhibits a timeout, the responsible peer's reputation value is decreased.

Wang and Li (2005) also considered a similar problem in which a peer needs to decide how much to charge for forwarding data. Instead of using an auction, a comprehensive utility function is used. The utility function captures many realistic factors: the quantitative benefits of forwarding data, the loss in delivering such data, the cost and the benefit to the whole community. With this utility function, an upstream peer has the incentive to contribute its forwarding bandwidth while a downstream peer is guided toward spending the upstream bandwidth economically. Furthermore, a reinforcement learning component is incorporated so that each peer can dynamically adjust the parameters in its utility function so as to optimally respond to the current market situations.

Sanghavi and Hajek (2005) observed that in a typical auction-based pricing mechanism as described above, there is a heavy communication burden on the peers. Indeed, the entire set of user preferences has to be communicated from a peer to the auctioneer. Sanghavi and Hajek then analytically derived a class of alternative information mechanisms that can significantly reduce the communication overhead. Specifically, each peer's bid is only a single real number in each case, instead of an entire real-valued function.

Figure 7: An example of the auction process in request forwarding (based on Gupta and Somani 2004)

Figure 8: An example of fully decentralized auction (based on Hausheer and Stiller 2005)

Hausheer and Stiller (2005) studied a completely decentralized auction approach for electronic P2P pricing of goods in a system called PeerMart (which is built on top of Pastry (Rowstron and Druschel 2001)). The key idea is the use of a broker set, which comprises other peers in the electronic marketplace. Specifically, a broker set consists of peers' whose IDs are closest to the ID of the good in the auction. Each of these peers then potentially acts as the auctioneer in the selling process. The advantage of the broker-set-based method is that in case a particular peer in the set is faulty (or even malicious in the sense that it does not respond to auction requests), another member in the set can take up the role of auctioneer. An example is shown in Figure 8.

Exchange-Based Systems

Motivated by the fact that any payment/credit-based system entails a significant transaction and accounting overhead, Anagnostakis and Greenwald (2004) proposed an exchange-based P2P file-sharing system. The fundamental premises is that any peer gives priority to exchange transfers. That is, in simple terms, any peer is willing to

send a file to a peer that is able to return a desired file. However, based on this idea, it is incorrect to consider two way exchanges only. Indeed, a "ring" of exchange involving two or more peers, as shown in Figure 9, is also a proper P2P file transfer.

In the exchange-based P2P file-sharing system, each peer maintains a data structure called incoming request queue (IRQ). Now, a crucial problem is how each peer can determine whether an incoming request should be entertained—i.e., whether such a request comes from some peer on a ring of exchange requests. It is obviously computationally formidable to determine all the potential multi peer cycles. Fortunately, Anagnostakis and Greenwald (2004) argue that based on simulation results, in practice a peer only needs to check for cycles with up to five peers.

Each peer uses a data structure called a "request tree" to check for potential request cycles. For example, as we can see in Figure 10, a peer A decides to entertain a request for file object o_2 because A finds that peer P_9 possesses an object that is needed by A . Based on this checking mechanism, the incoming requests are prioritized. Simulation

Figure 9: Different feasible forms of exchanges (based on Becker and Clement 2004)

Figure 10: Request cycle detection using the request tree data structure maintained at each peer (based on Becker and Clement 2004)

Table 2: A Qualitative Comparison of Different Incentive Approaches for P2P File Sharing

	Payment	Auction	Exchange	Reciprocity	Reputation
Example	Hausheer et al. (2003)	Gupta and Somani (2004)	Anagnostakis and Greenwald (2004)	BitTorrent	Sun and Garcia-Molina (2004)
Practical Implementation	Complex	Complex	Easy	Easy	Easy
Security Requirement	High	High	Low	Low	Medium
Centralized Authority Required	Yes	Yes	No	No	Yes/No
Scalability	Medium	Low	High	High	High

results indicate that the proposed exchange-based mechanisms are effective in terms of file object download time.

Table 2 gives a qualitative comparison of different incentive approaches proposed for P2P file-sharing systems. In general, systems that involve payment would be more difficult to implement because it is not trivial to design a global “currency” for use in such systems. Furthermore, security requirement would be high because the payment could be forged by malicious peers. On the other hand, exchange-based or reciprocity-based systems are easier to implement and hence, are more scalable. The major crux is that there is much less state information to be kept by each peer. More important, the accuracy of such state information (e.g., reputation) does not need to be absolutely very high. Thus, we expect that future P2P file sharing would still be based on similar approaches.

Media-Streaming Systems

In this section, we describe several interesting techniques for providing incentives in a P2P media-streaming environment. Broadly speaking, there are two different structures used in P2P media streaming: asynchronous layered streaming and synchronous multicast streaming.

Layered Many-to-One Streaming

Xu et al. (2002) proposed a fully distributed differentiated admission control protocol called DAC_{p2p} . In this model, each requesting peer needs multiple supplying peers to send different layers of media data. That is, from a topological perspective, each streaming session involves one

single recipient and multiple sources, structured as a two-level inverted tree. Of course, each supplying peer may also be a recipient of another logically different streaming session. With this streaming model, each requesting peer needs to actively contact several supplying peers in order to start a session.

This streaming model is based on a practical observation that peer requests are asynchronous and each peer’s communication capability is different (i.e., heterogeneous streaming capabilities), as illustrated in Figure 11, where peers with different communication supports (e.g., DSL, dial-up, etc.) initiate streaming requests at different times.

A layer-encoded media-streaming process is assumed, as shown in Figure 12. As can be seen, each peer performs buffered playback so that the received media data are kept in a buffer and thus, can be used for streaming to other later-coming peers. For example, H_1 initiates a streaming session first and thus, it is served solely by the server. Peer H_2 starts its session next and so it can request H_1 , which has buffered some media data, together with the server to send it the required data. Similarly, H_3 can stream from H_1 and H_2 without the server as it starts its session just in time to use the buffered data from the two earlier peers. On the other hand, H_4 , which starts too late, cannot stream from H_1 and H_2 . Instead, it receives media data from H_3 and the server.

Each potential supplying peer has only a limited capacity; thus, an admission control mechanism is needed. Peers in the system are classified into N classes according

Figure 11: Asynchrony and heterogeneity of media streaming peers (based on Cui and Nahrstedt 2003)

to the different levels of uploading bandwidth available at the peers. Each potential supplying peer P_s maintains an admission probability vector: $(Pr[1], Pr[2], \dots, Pr[N])$. Here, a smaller index represents a class with a larger uploading bandwidth. Suppose P_s is itself a class- k peer. Then, its probability vector is initialized as follows:

- For $1 \leq i \leq k, Pr[i] = 1.0$
- For $k < i \leq N, Pr[i] = \frac{1}{2^{i-k}}$

Thus, P_s always grants media-streaming requests from a higher-class peer (i.e., one that has a larger uploading bandwidth). Notice that this is similar in spirit to the incentive approach used in BitTorrent (Cohen 2003). For requests from lower-class peers, P_s may serve them as governed by the respective probabilities $Pr[i]$ in the vector. If P_s has not served any request during a certain period of time, then the admission probabilities of lower-class peers will be increased.

Similar to the case in BitTorrent, each peer has the incentive to report a higher uploading bandwidth because doing so will increase its probability of admission when it needs to initiate a media-streaming session. Xue et al. (2004) extended the DAC_{p2p} to a wireless environment.

The key idea in the extension is to exploit the spatial distribution of mobile devices to form clusters. Users in a cluster interact using the DAC mechanism.

Habib and Chuang (2006) also explored a similar idea in providing differentiated peer selection to participating peers. Specifically, a peer has only a limited set of choices (with possibly low media quality) if it behaves selfishly in the system. The degree of selfishness is reflected by a score known to other peers. The score is increased if the peer contributes to other peers, and is decreased if it refuses the requests of other peers. Based on a practical emulation study using the PROMISE (Hefeeda et al. 2003) streaming system implemented on top of PlanetLab (www.planet-lab.org) Habib and Chuang (2006) found that the proposed incentive scheme is effective in enhancing the performance of the system.

Multicast One-to-Many Streaming

Ngan, Wallach, and Druschel (2004) considered an application-level multicast system for video streaming. The system is based on SplitStream (Castro et al. 2003) which in turn is built on top of Pastry (Rowstron and Druschel 2001). The multicast system considered critically relies on a payment-based scheme. Specifically, there are five components:

- **Debt Maintenance:** When peer A forwards video-streaming data to a downstream peer B , B owes A a unit of debt.
- **Periodic Tree Reconstruction:** The multicast tree is reconstructed periodically in order to avoid prolonged unfair connections among peers. An unfair connection is one between a well-behaved peer and a selfish peer.
- **Parental Availability:** Any new peer can obtain location and addressing information about any potential parent peers in the multicast tree. Thus, the new peer can identify a potential selfish parent if the latter consistently refuses connection.
- **Reciprocal Requests:** In the system, any two well-behaved peers are expected to have an equal chance of being parent or child in any given multicast tree.
- **Ancestor Rating:** This is a generalization of the Debt Maintenance component. Here, debts are also accounted for all ancestors of a peer. Specifically, all nodes on a path in forwarding data from the source to a peer are credited or debited in cases in which expected data are successfully received or not, respectively.

Figure 12: Layered streaming with buffering for serving asynchronous requests (based on Cui and Nahrstedt 2003)

Figure 13: Layered video streaming using multiple multicast trees (based on Chu and Zhang 2004)

Simulation results indicate that a selfish free-rider is effectively penalized in terms of the amount of video-streaming data received.

Chu and Zhang (2004) also considered a multicast-based streaming environment. The streaming process is synchronous and is supported by a multiple description codec (MDC), in which a server provides several different stripes of video with different quality. A key feature in this streaming environment is that during each streaming session, multiple multicast trees are used, each of which is for sending different stripes of video. This is illustrated in Figure 13. With such a streaming structure, a peer can logically join different trees simultaneously at a different position in each tree. Specifically, when a peer joins a certain multicast tree at a higher level (e.g., peer A in the tree for stripe II), it needs to provide a larger uploading bandwidth to serve the lower-level peers in the same tree. On the other hand, a peer can also join a tree as a leaf so that it becomes a pure recipient in the tree.

With this model, Chu and Zhang (2004) then studied the effects of different degrees of altruism. They used a parameter $K = f/r$, where f is the total uploading bandwidth

provided by a peer and r is its total downloading bandwidth. Thus, a larger value of K indicates a higher degree of altruism for the peer. Similar to many other P2P sharing systems described above in this chapter, a peer with a higher value of K can enjoy a better performance (in terms of media quality in the streaming application). Simulation results indicate that a small average value of K (e.g., 1.5) can already improve the overall performance of the whole system.

Shrivastava and Banerjee (2005) demonstrated that streaming based on a multicast structure could be a result of natural selection. The key idea is depicted in Figure 14. The left part of the figure illustrates a situation in which multiple peers are sharing the capacity of a single server. As a result, each peer can enjoy only a small downloading data rate. However, when peers are organized as a multicast tree, based on strategic *natural selection* (detailed below), each peer can enjoy a much larger downloading rate.

The natural selection process is illustrated in Figure 15. Here, initially the root is the only source in the system and thus, peer A selects the root as the source, enjoying

Figure 14: A multicast streaming structure is better off for every peer (based on Shrivastava and Banerjee 2005)

Figure 15: An illustration of the strategic natural selection process in connecting streaming sources and destinations (BSE is the bootstrap entity providing service information) (based on Shrivastava and Banerjee 2005)

a downloading rate of 500 Kbps. Now, when a new peer B joins the system, peer A has basically two choices: (1) serve peer B; or (2) do not serve peer B. To implement the second choice, which seems to be a more favorable one, peer A can declare to the bootstrap entity (BSE) that its uploading rate is 0 or a value smaller than 250 Kbps (which is half the capacity of the root). However, in doing so, peer B has no choice, but naturally selects the root to be its streaming source. In that case, peers A and B will share the root's uploading capacity and thus, each obtains only a 250 Kbps data rate. On the other hand, in anticipation of such an actually unfavorable outcome, peer A should instead strategically declare its uploading bandwidth to be 300 Kbps, which is slightly higher than the capacity declared by the root. Consequently, peer A can continue to enjoy a high downloading rate from the root, at the expense of its uploading of data to peer B at a rate of 300 Kbps.

Ye and Makedon (2004) proposed a useful detection and penalty scheme to tackle the existence of selfish peers in a multicast streaming session. They observed that a selfish peer may lie to other peers in that it claims its uploading bandwidth is large so that it can enjoy a higher probability of being admitted into a streaming session or enjoy a higher quality of media data. The key of the detection mechanism is that a downstream peer in a multicast tree returns a "streaming certificate" back to its parent peer. For example, as shown in Figure 16, peers P_4 , P_5 , and P_6 , send streaming certificates $\mathbf{SCert}(P_i, P_3)$ to

the parent peer P_3 ($i = 4, 5, 6$). The certificates are sent periodically and are time-stamped with authentication. Thus, a higher-level peer (e.g., P_1) can periodically check whether its children peers (i.e., P_2 and P_3) are selfish by asking for certificates they have received (if any) from their own children peers. If a peer cannot produce such a certificate, the higher-level peer can then remove such a potentially selfish peer from the tree. The removal process is manifested as a termination of media-data transmission.

Jun et al. (2005) explored a similar idea in their proposed Trust-Aware Multicast (TAM) protocol. Targeted for detecting and deterring uncooperative peers, which can modify, fabricate, replay, block, and delay data, the TAM protocol is based on a message structure that contains four fields: sequence number, timeout period, data payload, and cryptographic signature. The sequence number is used for detecting duplicated or missing data. The timeout period is used for detecting delayed data. Thus, a selfish (or even malicious) peer can be identified by its children peers in the multicast tree. Different from the approach suggested by Ye and Makedon (2004), the children peers are responsible for reporting such suspicious selfish peers to the root (or the server) in the tree. Jun et al.'s scheme is also more flexible in that even upon receiving such "negative reports," the root may not discard such suspected selfish peers immediately. Instead, the root keeps track of a trust metric for each peer in the tree. A negative report only decreases the trust value. Only when the trust value

Figure 16: Detection and removal of a selfish peer from the streaming multicast tree (based on Ye and Makedon 2004)

falls below some threshold is the suspected selfish peer discarded from the tree and the peers under its sub tree are relocated.

INCENTIVE ISSUES IN WIRELESS P2P SYSTEMS

Wireless P2P systems (Hsieh and Sivakumar 2004) are proliferating in recent years. Thanks to the widely available hot-spot wireless environments, users' handheld devices can work with each other in an ad hoc and impromptu manner. As will be evident in this section, many techniques designed for wired environments are also applied in a wireless system in a similar manner. Nevertheless, there is a unique challenge in a wireless environment, namely the connectivity issue. Furthermore, there is also one more dimension of cost incurred in each wireless P2P user—the energy expenditure, which is of prime concern to the user as wireless devices are largely powered by batteries.

Routing and Data Forwarding

In a wireless P2P system, the connectivity among peers is itself a boot-strap sharing problem. Indeed, if wireless users are unwilling to cooperate in performing routing and data forwarding, the wireless network can become partitioned so that service providers cannot be reached by potential service consumers. In view of this critical challenge, there has been a plethora of important research results related to incentive issues for ad hoc routing and data forwarding. In the following, we briefly cover several interesting techniques that are based on payment mechanisms, auction mechanisms, reputation systems, and game theoretic modeling.

Ileri, Mau, and Mandayam (2005) proposed a payment-based scheme for enticing devices to cooperate in forwarding data for other devices in the network. The payment is

not in monetary terms but in terms of bits per Joule. Specifically, the utility of a user i in the network is defined as:

$$u_i(p_i) = \frac{T_i(p_i)}{p_i} \quad (10)$$

where u_i is the utility p_i is the transmit power, and T_i is the throughput. That is, the utility is equal to the average amount of data received per unit energy expended, also in bit per Joule.

The payment system also involves an access point in the wireless network. Specifically, the access point also tries to maximize its revenue by using two parameters, μ and λ , judiciously. Here, λ is the unit price of service provided by the access point to any device in the network. On the other hand, μ is the unit reimbursement the access point provides to any device that has helped forward other devices' traffic. The access point's revenue is therefore given by:

$$p = \sum_{\text{all users } i} \lambda T_{in_i} - \sum_{\text{all forwarders } j} \mu T_{ja}^{eff-for} \quad (11)$$

where T_{in_i} is the service provided by the access point to user i and $T_{ja}^{eff-for}$ is the service forwarded by a forwarder j to the access point. The situation is as shown in Figure 17.

Simulation results indicate that the proposed service reimbursement scheme generally improves the network aggregate utility.

Salem et al. (2006) also considered a payment-based scheme for encouraging cooperation. However, their scheme involves real monetary costs and a payment-clearance infrastructure (e.g., a billing account for each user). The charging and rewarding scheme is similar to that we described above—a forwarder will get reimbursed and a normal user using network service will get charged.

Figure 17: Charging of network service and reimbursement of data forwarding (based on Ileri et al. 2005)

Table 3: A Qualitative Comparison of Various Wireless Ad Hoc Data Forwarding Approaches

Proposed Approach	Incentive Scheme	Implementation Difficulty	Security Required	Major Drawback
Ileri et al. (2005)	Payment	Low	High	Energy-based currency
Salem et al. (2006)	Payment	High	High	Real money
Marbach and Qiu (2005)	Payment	High	High	Unlimited budget
Wang and Li (2005)	Auction	High	High	Communication
Buchegger and Le Boudec (2005)	Reputation	Low	Low	Trust
Felegyhazi et al. (2006)	Utility	Low	Low	Receiver's payoff

Marbach and Qiu (2005) investigated a similar problem based on individual device pricing. However, the main differences are that each device is allowed to freely decide how much to charge for forwarding traffic (in previous researches, usually the unit price is the same for all device) and there is no budget constraint on all the devices.

Wang and Li (2005) proposed an auction-based scheme similar to the work by Gupta and Somani (2004). Specifically, each device in a wireless ad hoc network declares its cost for forwarding data when some other device wants to initiate a multihop transmission. After considering all possible paths that are able to reach the destination device, the least-cost path is chosen and the devices on the path are paid for their forwarding. Again using a Vickrey-Clarke-Groves (VCG) based analysis, it is shown that the dominant action for each device is to report its true cost of forwarding. Wang and Li also showed that no truthful mechanism can avoid collusion between two neighboring devices in the forwarding auction game.

Buchegger and Le Boudec (2005) observed that while economic incentives such as payment approaches can entice selfish users to help in routing and forwarding data, they may not be able to handle other types of misbehaviors, such as packet dropping, modification, fabrication, or timing problems. Thus, they proposed to use a reputation system in which every user provides "opinion" data to the network based on observing the behaviors of neighboring devices. After a user device has gathered such opinions (both from itself or from others, i.e., second-hand information), it can carry out a Bayesian estimation so as to classify the neighboring devices as malicious or normal. A neighboring device that is identified as a malicious user is then isolated from the network by rejecting its routing and forwarding requests.

Felegyhazi, Hubaux, and Buttyan (2006) reported an interesting game theoretic analysis of the forwarding problem in ad hoc networks. Instead of using a payment-based strategy, the model uses a purely utility concept in that a device's utility is equal to its payoff when it acts as a data source (i.e., the sender of a multihop traffic), minus the cost when it acts an intermediate device (i.e., a forwarder of other sender's traffic) in any time slot. Here, both the payoff and the cost are defined in terms of data throughput. Thus, an important assumption in this model is that only the sender has a positive payoff, while all the intermediate devices enjoy no payoff but just incur forwarding costs. Specifically, the destination device

(i.e., the receiver of the multihop traffic) also enjoys no payoff. This may not conform to a realistic situation. Simulations were done to estimate the probability that the conditions for a cooperative equilibrium hold in randomly generated network scenarios.

Table 3 gives a qualitative comparison of various data-forwarding approaches in wireless ad hoc networks. In general, some form of payment is required. However, as the devices in a wireless ad hoc networks are not under a centralized authority's control, it is very difficult to enforce a secure payment-clearance mechanism. Auction schemes are interesting but are also difficult to implement in practice because a highly trusted communication infrastructure is required for exchanging bidding information. Yet this is a paradoxical requirement, as the communication among wireless peers is itself the ultimate goal in data forwarding. Similarly, a reputation-based approach, while not difficult to implement in practice, could also lead to a paradoxical situation in the sense that the reputation values may not be trustworthy.

Wireless Information Sharing Systems

Wolfson, Xu, and Sistla (2004) investigated an interesting opportunistic wireless information exchange problem in which a moving vehicle transmits the information it has collected to encountered vehicles, thereby obtaining other information from those vehicles in exchange. The incentive mechanisms suggested are based on virtual currency. Specifically, each mobile user carries some virtual currency in the form of a protected counter. Two different mechanisms are considered: producer-paid and consumer-paid. The producer of information pays in the former, while the consumer pays in the latter. The price P of a piece of information item (e.g., availability information about a parking lot) is given by:

$$P = E - t - \frac{d}{v} \quad (12)$$

where E is the gross valuation of the information item, t is the time elapsed since the information item is created, d is the distance to travel before the user of the information can reach the relevant location (e.g., the parking space), and v is the speed of the user. Simulation results under a simple situation in which there are only one consumer

Figure 18: System model for wireless data access (based on Yeung and Kwok, *IEEE Transactions on Mobile Computing*, 2006)

and two parking spaces indicate that the proposed incentive mechanisms are effective.

Yeung and Kwok (*IEEE Transactions on Mobile Computing*, 2006) considered an interesting scenario in wireless data access: a number of mobile clients are interested in a set of data items kept at a common server. Each client independently sends a request to inform the server of its desired data items and the server replies in the broadcast channel. Yeung and Kwok investigated the energy consumption characteristics in such a scenario.

Figure 18 depicts the system model for wireless data access. It consists of a server and a set of clients, N . The clients are interested in a common set of data items, D , which are kept at the server. To request a specific data item, d_a , client i is required to inform the server by sending an uplink request, represented by $q_i(d_a)$. The server then replies with the content of the requested data item, d_a , in the common broadcast channel. This allows the data item to be shared among different clients. As illustrated in Figure 18, both clients j and k request the same data item, d_c , in the second interval. However, the server is required to broadcast the content of d_c only *once* in the next broadcast period, which reduces the bandwidth requirement.

To successfully complete a query, a client expends its energy in two different parts: (1) informing the server of the desired data item, E_{UL} ; and (2) downloading the content of the data item from the common broadcast channel, E_{DL} . The energy cost of sending a request to the server is represented by E_s . If a client sends a request for each query, then E_{UL} would be the same as E_s . However, we show that clients need not send requests for each query even without caching. This implies that E_{UL} does not necessarily equal E_s . In general, the total energy required to complete a query E_Q , is given by:

$$E_Q = E_{UL} + E_{DL} \quad (13)$$

It is assumed that E_{DL} is the same for all clients, but its value depends on the size of a data item. In practice, E_s is a function of various quantities, including spatial separation, speed, instantaneous channel quality, bit-error rate requirement, etc. For simplicity, however, E_s is also assumed to be a fixed quantity.

Based on this model of wireless data access, a novel utility function for quantifying performance is defined as follows:

$$U_i = \frac{E_{total}}{E_Q^i} \quad (14)$$

where E_{total} is the total energy available. The objective is then to reduce the amount of energy consumed in the query process such that *every* client's utility (Equation 14) is increased.

Based on the utility function, Yeung and Kwok formulate wireless data access scheme as a noncooperative game—wireless data access (WDA) game. Game theoretic analysis shows that while the proposed scheme does not rely on client caching, clients do not always necessarily send requests to the server. Simulation results also suggest that the proposed scheme, compared with a simple always-request one, increases the utility and lifetime of every client while reducing the number of requests sent, at the cost of slightly larger average query delay. They also compared the performance of the proposed scheme with two popular schemes that use client caching. The simulation results show that caching only benefits clients with high query rates while resulting in both shorter lifetime and smaller utility in other clients.

Network Access Sharing

Efstathiou and Polyzos (2003) studied the problem of building a federation of wireless networks using a fully autonomous P2P approach. Specifically, in their system model, there are multiple wireless local area networks (WLANs), each of which is considered to be completely autonomous. When a user of one WLAN enters the domain of a different nearby WLAN, the latter would also admit the user based on reciprocity. To achieve this, each WLAN is equipped with a domain agent (DA), which is responsible for managing the roaming of foreign users. Each DA maintains a counter of tokens, which is increased when a foreign user is admitted to its WLAN and is decreased when a local user travels to a foreign WLAN. The DAs of different WLANs interact with each other in a pure P2P fashion. Thus, the advantage of this approach is that there is no need to set up prior pairwise administrative agreements among different WLANs.

Based on a prototype built using Cisco WLANs, it is found that the proposed P2P based roaming scheme is efficient.

Kang and Mutka (2005) considered an interesting problem in which peers share the access cost of wireless multimedia contents. Specifically, one peer in the network serves as a proxy, which pays a network server in order to download some multimedia contents in a wireless fashion. Other peers in the system then share the contents without incurring any cost. This is achieved by having the proxy broadcast the received multimedia data to the peers within its transmission range. For other distant

Figure 19: Illustration of network access cost sharing (left), and round-robin scheduling of proxy (right) (based on Kang and Mutka 2005)

peers, rebroadcasting by the edge peers is used to serve them. This is illustrated in Figure 19 (left side).

This idea of cost sharing in wireless data access is called CHUM (cooperating ad hoc networking to support messaging). A key component in such sharing is the cost sharing mechanism. In the CHUM system, the peers take turn, in a round-robin manner, to serve as the proxy. This is illustrated in Figure 19 (right side). It is assumed that the peers have the incentive to follow this round-robin rule based on the reciprocity concept. Simulation results indicate that 80% of network access cost is saved even with just six peers in the system.

DISCUSSION AND FUTURE WORK

We have seen that in both wired and wireless systems, the major techniques for providing incentives are payment (virtual or real), exchange (barter), reciprocity (pairwise), reputation (global), and game theoretic utility. Payment-based systems work by exploiting a user's incentive in increasing or even maximizing its "revenue." However, such an incentive may not be appropriate in some practical situations. For instance, a cellular phone user may not be interested in his or her income (from such sharing) but care more about the quality of service derived from the device. Exchange-based systems fit very well in file sharing applications because users have strong incentives for trading files of interest (e.g., music files). For other applications such as forwarding of data (e.g., in wireless ad hoc networks), it is debatable as to whether in practice a user would be interested in exchanging data-forwarding capabilities. Reciprocity (in a pairwise manner) is similar in spirit as an exchange-based mechanism. The major difference is that exchange is usually memoryless, in that every exchange transaction is treated as a rendezvous event, while general reciprocity is achieved when devices help each other at different times. Thus, such a difference leads to the requirement that users have to keep memory about the prior transactions so that users can "pay back" each other. Because of this history-based feature, reciprocity mechanisms suffer from one drawback—a user may be out of the system when he or she

needs to pay back. Such a possible "future loss" may deter a user from genuinely contributing to the community for the fear of not getting deserved pay back. Reputation-based systems can be seen as a generalized form of reciprocity. Specifically, while reciprocity is about a particular user pair, a reputation value is a global assessment perceived by all users in the sense that the reputation value is computed by using observations made by many different users. By nature, similar to reciprocity mechanisms reputation systems require substantial memory, centralized or distributed, for recording the reputation values. Thus, it seems that such a system is more suitable for situations in which there is a persistent entity, which is logically external to the P2P system, for keeping track of the reputation values. For example, such an entity may be a centralized auctioneer in an electronic auction community, or the base station (access point) in a wireless network. Game theoretic incentive mechanisms are convincing in the sense that the utility function used can usually cover a multitude of important metrics. But the problem is that it is sometimes difficult to achieve an efficient distributed implementation of the resultant protocols.

Perhaps other than in an exchange-based system, which involves "stateless" interactions, all other incentive mechanisms could suffer from tampering or fabrication of the "incentive parameter" used: the money (virtual or real) in a payment-based system, the reciprocity metric, and the reputation value. Thus, additional mechanisms, usually based on cryptographic techniques, are needed to guard against such potential malicious attacks to the incentive mechanisms. In particular, whitewashing is widely considered to be a very low-cost technique for a selfish or malicious user to work around the incentive scheme.

Obviously, there is plenty of room for future research about incentive mechanisms in P2P sharing environments. Most notably, revenue maximizing (Yeung and Kwok, PIMRC 2006) in a hybrid P2P system (e.g., the so-called converged wireless architecture, in which an infrastructure-based cellular network is tightly coupled with P2P WLANs) is of a high practical interest because there are more and more cellular subscribers trying to share their

resources without the intervention of the cellular service provider. In a data-sharing environment, server peer selection (Leung and Kwok, *Efficient and Practical Greedy Algorithm*, 2005) is another important direction because we believe that users care more about the quality of service achieved than about the revenue or cost they incur in participation. In economic terms, people, especially wired or wireless game players, are quite inelastic about the costs. Nevertheless, energy conservation (Leung and Kwok, *Energy Conservation*, 2005; *Community-based Asynchronous Wakeup Protocol*, 2005) is still of a prime concern in any wireless P2P sharing network because energy depletion cannot be compensated in any way by increased revenue generated in a payment-based sharing system. Thus, perhaps in a game theoretic setting, we should incorporate energy expenditure in the utility function. Finally, topology control (Leung and Kwok, *On Topology Control*, 2005) in a wired (overlay networks) or wireless (ad hoc networks) is also important in the sense that sharing is usually interest-based, meaning that users naturally form clusters with similar interests, and as such, related users would be more cooperative in following the incentive protocols. Consequently, building an interest-based sharing topology could be helpful in enhancing the effectiveness of sharing.

CONCLUSION

In this chapter, I have presented a detailed survey of incentive techniques for promoting sharing (discrete or continuous data) in a peer-to-peer system. I have considered well-known mechanisms that are proposed and have been deployed in the Internet environment. The techniques used can be classified into payment-based, exchange-based, reciprocity, reputation, and game theoretic. These techniques are also applicable in general to a wireless environment. However, a wireless P2P system, while still in its infancy, has a unique challenge—the connectivity among devices is by itself a crucial “sharing” problem (sharing of energy and bandwidth). Much more work needs to be done in related problems such as revenue maximizing (or pricing) in a hybrid wireless P2P system, intelligent peer selection in a data-sharing network, energy-aware incentive mechanisms, and interest-based topology control. Furthermore, in systems that require payments or some form of critical information items (e.g., reputation values), the security aspect needs to be properly addressed.

Finally, we can see that the amounts of work done in the areas of media streaming and wireless P2P systems are much smaller than that in the area of file sharing. This indicates that these two areas are wide open and are a fertile ground for further research.

ACKNOWLEDGMENT

This research was supported by the Hong Kong Research Grants Council (under project number HKU7157/04E). Thanks are due to Mr. Tyrone Kwok for his kind assistance in compiling the figures in this article. The author would also like to thank Professor Hossein Bidgoli for his professional advice in preparing this chapter. Finally

the author would like to sincerely thank all the six anonymous reviewers for their insightful and constructive comments.

GLOSSARY

Altruism: A situation in which participants unselfishly contribute to the community.

Auction: A situation in which participants compete for ownership of an item by declaring a high price. The participant that gives the highest price wins the item.

Exchange: In the P2P computing context, the situation in which peers trade services in a rendezvous manner.

Free-Riding: Selfish participants in a community that only take advantage of others, without contributing.

Incentives: Valued entities that can motivate autonomous decision makers in a community to cooperate.

Nash Equilibrium: A situation in a strategy game in which no participant can benefit by unilaterally changing his or her decision.

P2P File Sharing: A peer-to-peer decentralized network of autonomous computers that share files among each other without intervention of any centralized authority.

P2P Media Streaming: A peer-to-peer decentralized network of autonomous computers that obtain media data from one or more peers in the network without intervention of any centralized authority.

Reciprocity: In the P2P computing context, the situation in which peer A “pays back” services to peer B who has previously contributed to peer A. That is, the return of a favor does not necessarily occur in a rendezvous manner.

INTRODUCTION

The volume and value of enterprise data have been growing faster than the speed at which traditional backup utilities' effectiveness has been increasing. Enterprises have become more dependent on their online systems and cannot ensure the availability of these data by relying only on traditional, network-bottlenecked, server-attached storage systems. Solutions to this problem have been offered by storage area network (SAN) technology, which provides enterprises with serverless zero-time-windows backup. In this new backup approach, backed-up data are removed to a secondary remote storage device, and the enterprise server becomes off-loaded, permitting high-performance continuous access to both applications and data. The objective of a SAN is to allow multiple servers access to a pool of data storage in which any server can potentially access any storage unit. In this environment, management plays a large role in providing security guarantees (with authorization to access particular storage devices) and sequencing or serialization guarantees (with authorization to access a particular device at certain time-point) (Server Clusters 2003).

A SAN fabric is usually based on fibre-channel technology that allows up to 10-km long-distance connections. This feature has a significant advantage in a campus environment, where reliable backup resources can be shared among several divisions. For example, fibre-channel SANs for a health care enterprise allow 24/7 continuous operation, patient record backup, and medical image archiving (Farley 2001).

The SAN becomes a key element of the enterprise environment in which data availability, serviceability, and

reliability are critical for a company's business. Many enterprise solutions (e.g., ATTO FibreBridge products, rack mount solutions, ATTO FibreCenter3400R/D, host bus adapters, the ATTO Diamond array, Compaq Storage Works products, EMC Connectrix solutions, LSI Logic E4600 Storage System) are available today. They can be effectively used in multiple platform storage-infrastructure solutions for data-intensive applications such as e-commerce, online transaction processing, electronic vaulting, data warehousing, data mining, Internet/intranet browsing, multimedia audio/video editing, high-definition television (HDTV) streaming, and enterprise database management applications (Riabov 2004).

This chapter describes fundamentals of storage area networks (SANs), their architectural elements (interfaces, interconnects, and fabrics), technologies (fibre-channel-arbitrated loop transport protocol, Brocade's configurations, InfiniBand switched-fabric architecture, Crossroad systems with a storage router, virtual interface architecture, direct access file system, Internet protocol (IP) storage technologies, SANs over IP, fibre channel over IP, Internet fibre-channel protocol, Internet SCSI, storage over IP, fabric shortest path first protocol, storage resource management, and adaptive network storage architecture), solutions, standards, associations, initiatives, forums, coalitions, vendors, and service providers.

SAN OVERVIEW

What Is a SAN?

A SAN (storage area network) is a networked high-speed infrastructure (subnetwork) that establishes direct access

by servers to an interconnected group of heterogeneous data-storage devices such as optical disks, redundant arrays of inexpensive disks (RAIDs), and tape backups (or tape libraries). SANs are effective for storing large amounts of information and backing up data online in e-commerce, online transaction processing, electronic vaulting, data warehousing, data mining, multimedia Internet/intranet browsing, and enterprise-database-managing applications. SANs provide additional capabilities (fault tolerance, remote management, clustering, and topological flexibility) to mission-critical, data-intensive applications (Troppens, Erkens, and Müller 2004). A SAN is typically a part of an enterprise network of computing resources (Sachdev and Arunkundram 2002). A simple model of the storage area network as a networked high-speed infrastructure is shown in Figure 1.

A SAN can be considered as an extended and shared storage bus within a data center, consisting of various storage devices and specific interfaces (e.g., fibre channel, enterprise system connection [ESCON], high-performance parallel interface [HIPPI], small computer system interface [SCSI], or serial storage architecture [SSA]) rather than Ethernet (Peterson 2006). In order to be connected to the enterprise network, the SAN uses technologies similar to those of local area networks (LANs) and wide area networks (WANs): switches, routers, gateways, and hubs (see Figure 1). WAN carrier technologies, such as asynchronous transfer mode (ATM) or synchronous optical networks (SONET), can be used for remote archival data storing and backup. As an important element of modern

distributed networking architectures of storage-centric enterprise information processing, SAN technology represents a significant step toward a fully networked secure data storage infrastructure that is radically different from traditional server-attached storage (Clark 2003). In addition, SANs provide improved options for network storage, such as a creation of remote or local, dedicated or shared data storage networks with access capability faster than network attached storage (NAS) (Preston 2002).

A SAN can be divided into four separate segments (SAN School 2006): (1) all the hardware (e.g., switches, cables, disk arrays, tape libraries, etc.), (2) protocols (fibre-channel arbitrated loop [FC-AL] and fibre-channel switch fabric [FC-SW]) that are used for communicating between the hardware parts, (3) hardware and software vendors, and (4) various computer applications that benefit from using SAN. A SAN can be viewed as a composition of three layers (see Figure 1): (1) host layer that includes host bus adaptors (HBAs), drivers, host operating systems, and interface software, (2) fabric layer (hubs, switches, fabric operating systems, and cabling, and (3) storage layer (disks, tapes, and advanced storage software).

SANs are based on the storage-centric information-processing paradigm, which enables any-to-any connectivity of computers (servers) and storage devices over a high-speed enterprise network of interconnected fibre-channel switches that form the SAN fabric. The incidence of unconnected clusters of information is eliminated or significantly reduced by SANs. According to this concept, a SAN resides behind the server and provides any

Figure 1: Storage area network as a networked high-speed enterprise infrastructure (NT = Windows NT)

users or devices on the enterprise network (“clients”) with fast access to an array of data-storage devices. Multiple servers and workstations from various vendors, running different operating systems, can all be connected to a SAN by using fiber-optic cabling (either a single or dual connection) and a special fibre-channel card called a “host bus adaptor” (HBA) (Anderson 2006).

A SAN can be viewed as multihost connected-and-shared enterprise storage. Adding new storage devices and server elements resolves traditional network bottlenecks and small-scale problems of interfaces, such as SCSI and NAS, and can easily expand the scale of the SAN (Thornburgh and Schoenborn 2001). Another advantage of SAN technology is that backups can be made over the SAN fibre-channel subnet, and, in this case, backup traffic is totally removed from the enterprise network.

SANs can offer high availability of operations because of a fully redundant architecture supported by three building blocks: server clustering, multipathing, and storage replication (Anderson 2006). Server clustering, load balancing, and autorecovering after a primary server failure are the principal elements of high-availability computing with a SAN. Multi-pathing uses redundant components to guard against failure of any connection component (HBA, switch, cable, or array controller) by rerouting traffic from one component to the other. Small enterprises widely use storage replication between servers connected to a SAN over an IP network. This enables one-to-one, one-to-many, and many-to-many replication, and data are synchronized in incremental blocks to minimize network traffic.

The SAN represents a new segment of the information services industry called storage solution providers (SSP). However, isolated SANs cannot realize all SSP services, such as real-time data replication, storage hosting, and remote vaulting. A server cluster uses virtual servers to failover services from one server to another. A service runs on one server in the server cluster, and then if the server fails, another server loads the virtual server. The database must be located on shared storage that can be accessed by all servers in the server cluster.

Benefits of SANs

A SAN makes physical storage capacity a single, scalable resource and allows the flexible allocation of virtualized storage volumes (e.g., RAIDs, just a bunch of disks/drives [JBODs], and EMC, Sun, and Dell storage devices). Centralization of data storage into a single pool allows storage resources and server resources to grow independently, and allows storage to be dynamically assigned from the pool. The SAN can manage backup tasks that were a huge administrative and computer-resource burden under old storage architectures. Common infrastructure for attaching storage allows a single common management model for configuration and deployment (Server Clusters 2003). The storage management cost savings can be higher than 80%. A cost-effective, scalable SAN enhances overall system performance. It can integrate legacy SCSI devices, which allows increasing their systemwide effective usable capacity by up to 30% (InfraStor 2002).

SANs are an integral part of large financial services enterprises, Internet service providers (ISPs), government

organization, research laboratories, electronic publishers, digital video production groups, TV-broadcasting stations moving to digital services, educational institutions, or any organization with increasing data storage needs.

There are several key reasons for implementing a SAN (InfraStor 2002). The first three concern business issues of return on the investment in data storage, as well as the protection of existing investments:

- SANs are cost-effective (reduced cost of storage management, including backup and recovery; increased user productivity; cost-effective implementations of high-availability disaster protection, using remote clusters and remote mirrored arrays).
- SANs reduce business risk (faster disaster recovery; reduced revenue loss from down-time; reduced lost-opportunity costs).
- Legacy investments are protected (SANs can be implemented without abandoning existing storage infrastructures such as devices using SCSI connections).

The next four reasons for using SANs address critical technical issues that face data-center managers at a time when the volume of data to be managed and made available in many organizations is increasing at an annual rate of 60% (InfraStor 2002):

- SANs provide scalability (add servers and storage independently).
- SANs allow flexibility (reconfigure storage and servers dynamically without interrupting their services; load sharing and redistribution); any additional tape or disk storage subsystems can be added to the SAN fabric dynamically.
- SANs enhance overall system performance (more effective use of existing server compute cycles; real-time backup without impacting LAN/WAN; multiple server-to-storage paths; networked storage arrays that can outperform bus-attached storage; compatibility with parallelized database applications).
- SANs are an integral part of any high-availability plan (facilitation of shared online spares and remote backup or mirroring; reduced down-time requirements; storage independent of the application and accessible through alternative data paths such as found in clustered systems).

With modern SAN architectures, enterprise data are available from 99.99% of the time to 99.999% of the time. This translates to down-time ranging from 53 minutes per year to 5 minutes per year. Also, the SAN implementation allows performing data replication to remote sites for significantly faster recovery in the event of a disaster. With SANs, data replication can be applied to storage at the controller, switch, or operating system level; this provides the capacity to create multiple copies of critical data and then move those copies to other parts of the SAN, or over a wide area network for remote protection (Storage Area Networks 2006).

The implementation of a SAN can realize significant overall cost savings in data-center operations and can

increase user productivity. The opportunity to avoid escalating costs depends on decentralization of data and applications. A key element in the consolidation of data storage must include the implementation of a basic SAN infrastructure in order to provide the following (InfraStor 2002):

- Bandwidth to service clients;
- Maintenance of data availability without impacting LAN bandwidth;
- Scalability for long-term, rapid growth with protection of legacy investments
- Flexibility to provide optimal balance of server and storage capacity
- Manageability for ease of installation and maintainability
- Shared access to data resources for real-time backup and recovery
- Administrators can support over 40% more storage in a SAN environment than in direct-attached environments (Storage Area Networks 2006).

Distributed environments require high-cost maintenance in terms of staff resources. The consolidation of distributed NT-based storages to a virtualized SAN-based resource can save 80% or more of the costs of management (InfraStor 2002).

SAN Applications

SAN applications cover the following areas of data transfer (Peterson 2006): (1) externalization of data storage out of the server—SAN-attached storage (SAS) and NAS-with-SAN-interconnects network architectures; (2) clustering, a redundant process that provides failover, high availability, performance, and scalability through the use of multiple servers as a data pipe and allows data storage resources to be shared; (3) data protection solutions for backup, remote clustering, file mirroring, and replicating and journaling file systems by creating data storage redundancy on a dynamic basis; (4) data vaulting, which is the process of transferring archived data to less expensive media; (5) data interchange from one storage system to another or between different environments; and (6) disaster recovery, which is similar to data interchange, moving copies of data offsite, and is built on remote vaulting (backup) processes or on remote array mirroring or clustering.

Several new applications benefit from 2 Gb/s fibre-channel SANs (Hammond-Doel 2001): multimedia audio/video servers that provide the ability to stream higher-resolution files, medical imaging, prepress that speeds up design and file preparation, and video editing of uncompressed HDTV data.

The first effective application of SANs has been serverless backup, which provides enterprises with full-time information availability. All backup-related tasks have been relegated to the SAN. Large enterprises can store and manage huge amounts of information (several terabytes or more) in the SAN high-performance environment. Enterprise servers are connected to storage devices (e.g., RAID5) via a high-speed interconnection, such as a fibre

channel. The SAN any-to-any communication principle provides the ability to share storage resources and alternative paths from server to data storage device. A SAN is also able to share the resources among several consolidated servers (Riabov 2004).

A cluster of interconnected servers may be connected to common storage devices in the SAN environment and be accessible to all clients. Modern enterprises use this clustering technology to resolve several challenging application problems (Barker and Massiglia 2001, 244)—i.e., providing customers, partners, and employees with continuous application service, even if the enterprise systems fail, and supporting application performance growth as demand grows, without service disruption to customers. Clusters provide load balancing, high availability, and fault tolerance and support application scaling. In some implementations, the clustered servers can be managed from a single console. Clustering methods are effectively used in e-commerce, online-transaction processing, and other Web applications, which handle a high volume of requests.

SAN methods have their roots in two low-cost technologies: SCSI-based storage and the NAS-based concept. They both successfully implement storage-network links, but are limited to a low volume of data flows and rates. SCSI still remains the most popular “bus-attached” server-storage connection in SAS systems, especially at the stage of transition from SCSI bus devices to fibre-channel switches using the SCSI-fiber protocol converter in a new enterprise storage (“data center”) environment. In a NAS system, storage elements (i.e., a disk array) are attached directly to any type of network via a LAN interface (e.g., Ethernet) and provide file access services to computer systems. If the NAS elements are connected to SANs, they can be considered as members of the SAS system. The stored data may be accessed by a host computer system using file access protocols such as network file system (NFS) or common Internet file system (CIFS).

SANs provide high-bandwidth block storage access over long distance via extended fibre-channel links. However, such links are generally restricted to connections between data centers. NAS access is less restricted by physical distance because communications are via TCP/IP (InfraStor 2001). NAS controls simple access to files via a standard TCP/IP link. A SAN provides storage access to client devices, but does not impose any inherent restrictions on the operating system or file system that may be used. For this reason, SANs are well suited to high-bandwidth storage access by transaction-processing and database-management system (DBMS) applications that manage storage access by themselves. NAS, which has the inherent ability to provide shared file-level access to multiple operating system (OS) environments, is well suited for requirements such as Web file services, computer-aided design (CAD) file access by combined WinNT/2000, UNIX, and LINUX devices, and wide-area streaming video distribution (InfraStor 2001). A balanced combination of these approaches will dominate in the future. See chapter on *Storage Area Networks: Architectures and Protocols*. Also see chapters on *Backup and Recovery System Requirements* and *Evaluating Storage Media Requirements*.

SAN Architecture and Infrastructure

SAN architectures have been changed evolutionarily, adapting to new application demands and expanding capacities. The original fibre-channel-based SANs were simple loop configurations based on the fibre-channel arbitrated loop (FC-AL) standard. Low-cost loops are easily expanded and combined with up to 126 hosts and devices, but they are difficult to deploy and have significant limitations on overall bandwidth. Requirements of scalability and new functionality had transformed SANs into fabric-based switching systems (fibre-channel switch fabric [FC-SW]) that could support up to 16 million hosts and devices. Numerous vendors offered different proprietary solutions of problems based on fabric switching. As a result, immature and competing standards created various interoperability problems. Homogeneous high-cost SANs were developed. Ottem (2001) refers to this phase as the “legacy proprietary fabric switch phase.” The modern established architectural approach is associated with a standards-based “Open” 2-Gb fabric switch that provides all the benefits of fabric switching, but is based on new industry standards (FC-SW-2) and an interoperability architecture that runs at twice the speed of legacy fabric. The standards-based switches provide heterogeneous capability, fault isolation, and rerouting. The introduction of industry standards, as a substitute for proprietary standards, has reduced the price of SAN components and management costs of running a SAN.

The Open 2-Gb fibre channel allows doubled SAN speeds, enables greater flexibility in configuring SANs for a wide range of applications, and is especially useful for managing 1.5-Gb high-definition video data. In HDTV applications, a single fiber can carry a full high-definition video stream without having to cache, buffer, or compress the data. Other examples (Ottem 2001) include storage

service providers that must deliver block data from and to users at the highest possible speeds and e-commerce companies that have to minimize transaction times. The 2-Gb fibre channel provides the high-speed backbone capability for fibre-channel networks, which can be used to interconnect two SAN switches. This configuration increases overall data throughput across the SAN even if servers and disk subsystems continue to operate via 1-Gb channels.

The fibre-channel (FC) data-storage industry has begun the transition to the 10-Gbps interface standard. The Technical Committee T11 of the International Committee for Information Technology Standards (INCITS) has developed the 10GFC project proposal (also known as FC-PI-2) that describes the fibre-channel physical layer for the transport of data at a rate of approximately 10 Gbps (Technical Committee T11 2006).

The new 4-Gbps technology for storage arrays has been announced (Lyon and Sturgeon 2006). It will significantly improve the sequential operations, such as database backups, long database loads, and streaming media. SAN implementations that make extensive use of interswitch links (ISLs) will also benefit from 4-Gbps technology (Business Brief 2006). It allows reducing the number of ISLs required and freeing up ports otherwise used for bandwidth aggregation.

Characteristics of four generations of SANs are summarized in Table 1.

A SAN system consists of software and hardware components that establish logical and physical paths between stored data and applications that request them (Sheldon 2001). The data transforms, which are located on the paths from storage device to application, are the four main abstract components (Barker and Massiglia 2001, 128): the disks (viewed through ESCON, FCP, HIPPI,

Table 1: Four Generations of SANs

	Fabric	Main Characteristics	Applications
First-Generation SANs	1-Gb loop	FC-AL protocol; 1-Gb speed; enabled first SANs	SCSI replacement
Second-Generation SANs	1-Gb proprietary; legacy fabric	FC-SW protocol; 1-Gb speed; proprietary switch-to-switch connections; expensive	LAN-free backup; high-availability clustering
Third-Generation SANs	2-Gb open fabric	Open FC-SW-2 protocol; 2-Gb speed; standards-based switch-to-switch connections; competition-driven price reductions	Serverless backup; heterogeneous storage consolidation; high-definition video data; virtualization
Fourth-Generation SANs	4–10-Gb fabric	10GFC-IP-2 protocol; 4–10-Gb speed	Medical imaging; streaming video; data mining; database backups; long database loads

SCSI, and SSA interfaces as abstract entities), volumes (logical/virtual disk-like storage entities that provide their clients with identified storage blocks of persistent/retrieved data), file systems, and application-independent database-management systems. In a system with a storage area network, five different combinations (Barker and Massiglia 2001) of these data transforms and corresponding transformation paths serve different applications and system architectures by various physical system elements. The disk abstraction is actually the physical disk drive. The abstract volume entity is realized as an external or embedded RAID controller, as an out-of-band or in-band SAN appliance, or as a volume manager serving a database or an application. Storage servers (such as NAS devices), database servers, and application servers may contain the abstract file systems. These devices and servers can be clustered to increase scaling and application availability. In that case, their volume file and management systems should be cluster-aware (Barker and Massiglia 2001).

Any SAN-based client-server system consists of three architectural components: interfaces, interconnects or network infrastructure components (switches, hubs, routers, bridges, gateways, multiplexers, extenders, and directors), and fabrics. The SAN interfaces are fibre channel, ESCON, HIPPI, SCSI, and SSA. The SAN interconnects link these storage interfaces together, making various network configurations.

The SAN infrastructure (fabric) includes the hardware, cabling, and software components that transmit data within the SAN. Fibre-channel switches and host bus adapters (HBAs) form the foundation, enabling servers and other storage devices to connect to one another (Anderson 2006). Since 1999, most HBAs support both FC-AL and FC-SW standards. However, HBA's configuration is not automatic in many cases, and it is important to verify from the switch side that the hosts are operating in the appropriate mode (Server Clusters 2003).

The fundamentally different fibre-channel topologies (point-to-point, FC-AL, and FC-SW) use different components to provide the infrastructure: (1) hubs, (2) switches, and (3) bridges and routers. Hubs are the simplest form of fibre-channel devices and are used to connect devices and hosts into arbitrated loop configurations. Hubs are typically half-duplex and have four, eight, twelve, or sixteen ports, allowing up to sixteen devices and hosts to be attached. However, the bandwidth on a hub is shared by all devices on the hub (Server Clusters 2003). Because of these performance constraints, hubs are used in small and/or low-bandwidth configurations.

Switches increase the overall SAN bandwidth by connecting system elements for data transmission and provide the advantages of the centralized storage repositories with shared applications and central management (IP Storage Area Networks 2006). A fabric switch provides the full fibre-channel bandwidth to each port independently. Typical switches allow ports to be configured in either an arbitrated-loop or a switched-mode fabric. In an arbitrated-loop configuration, the ports are typically full bandwidth and bidirectional, allowing devices and hosts to communicate at full fibre-channel speed in both directions simultaneously. Switches are the basic

infrastructure used for large, point-to-point, switched fabrics. In this mode, a switch allows any device to communicate directly with any other device at full fibre-channel speed (1 Gbps or 2 Gbps) (Server Clusters 2003). Switches typically support 16, 32, 64, or even 128 ports. Switches can detect failed or congested connections and reroute data to the correct device. Linked (cascaded) switches increase the number of available SAN connections. This provides greater performance and resilience against individual connection failures (Anderson 2006).

Routers and bridges perform protocol transformations in SANs that allow different interconnect technologies to interoperate. The most common SAN fabrics are switched fibre channel, switched SCSI, and switched SSA, all of which physically link the interconnects and determine the SAN's performance and scalability (Simitci 2003). Some fabrics embed operating systems that provide for SAN security, monitoring, and management. Hosts are connected to the fibre-channel SAN through HBAs, which consist of hardware and interface drivers. Fibre-channel HBAs support negotiation with network-attached devices and switches and allow the host to minimize its CPU overhead.

SAN architectures are of two types: (1) "proprietary," those that are sourced from a single manufacturer who serves as the single point of contact for SAN hardware, software, and services, and (2) "open" architectures that consist of hardware and software from more than one manufacturer (Storage Area Networks 2003). Proprietary SAN architectures are usually limited in flexibility, because a hardware manufacturer could have limited experience in some specialized areas, such as tape library, software configuration, or storage management. Open-SAN architectures are more flexible. The issue of SAN integration with multivendor technologies is critical to ensure functionality, interoperability, and optimal performance. Ensuring data integrity guarantees and enforcing security policies for access rights to a particular storage device is a core part of the infrastructure (Server Clusters 2003). See chapter on *Storage Area Networks: Architectures and Protocols*.

SAN Design and Management Issues

The main benefit of SANs is that storage can be managed as a centralized pool of resources. The data storage infrastructure must be designed to provide highly available access so that the loss of one or more components in the storage fabric does not lead to servers being unable to access the application data. This principle is implemented in the following ways (Server Clusters 2003):

- There is no single point of failure of cables or components such as HBAs, switches, or storage controllers.
- Transparent and dynamic path detection and failover are implemented at the host. These features are supported by multipath drivers running on the host to present a single storage view to the application across multiple, independent HBAs.
- Almost all components (HBAs, switches, and controllers) have built-in hot-swap and hot-plug utilities for adopting interface cards, memory, CPUs, and disk drives.

Different SAN designs are based on the following topologies: (1) multiple independent fabrics, (2) federated fabrics, and (3) core backbone (Server Clusters 2003).

In the case of a multiple fabric configuration, each host or device is connected to multiple fabrics, but switches are not linked. In the event of the failure of one fabric, hosts and devices can communicate using the remaining fabric. In this configuration, each fabric should have the same zoning and security information to ensure a consistent view of the fabric regardless of the chosen communication port. Also, hosts and devices must have multiple adapters, which are treated as different storage buses. Additional multipathing software (e.g., EMC PowerPath™ or Compaq SecurePath™) is required to ensure that the host gets a single view of the devices across the two HBAs.

In the case of a federated fabric, individual hosts and devices are connected to at least two switches, which are linked together. This configuration has many management advantages (e.g., only one set of zoning information and one set of security information is managed; fabric itself can route around various link failures and switch failures, etc.). However, a disadvantage of this approach means that management errors can propagate to the entire fabric.

A core backbone configuration is frequently used (Server Clusters 2003). The core of the fabric is built using highly scalable, high-performance switches where the interswitch connections provide high-performance communication (e.g., 8 to 10 Gbps). Redundant edge switches can be cascaded from the core infrastructure to provide high numbers of ports for storage and hosts devices. As in the two previous configuration cases, additional multipathing software is required to ensure that the host gets a single view of the devices across the two HBAs. Also, management errors can propagate to the entire fabric.

SAN Operating System Software Components

The SAN software plays an important role in providing an environment for various business and management applications, called “system applications” (Barker and Masiglia 2001, 13). These include clustering, data replication, and data copying. The management applications (zoning, device discovery, allocation, RAID subsystems, and others) manage the complex environment of distributed systems. These applications can significantly reduce the cost and improve the quality of enterprise information services.

In particular, SAN management software provides the following services (Anderson 2006):

- Configuration and optimization of individual components of the best setup
- Monitoring of the entire network for performance bottlenecks and areas of potential failure
- Automation of time-consuming tasks such as data backup
- Management of all available storage system components as one virtual pool
- Statistics overview

Microsoft Corp. has launched the Simple SAN Program (Storage Management 2006) to ensure that customers

deploying Windows Server 2003-based SANs have the appropriate tools for a simplified installation and management experience.

SAN Security Issues

The specific security issue of technology containment associated with a SAN also has to be addressed (Storage Area Networks 2003). For example, Windows NT servers would claim every available logical unit number (LUN) visible to them. Technology containment keeps servers from gaining unauthorized or accidental access to undesignated areas, such as data access and fabric management security, within the SAN.

The data access and security methodologies include: (1) fabric zoning, which provides a fabric port-and-host/storage-level point of logical partitioning and can help ensure that different OS types or applications are partitioned on the SAN (Server Clusters 2003); (2) LUN Masking, which is configured at the RAID storage subsystem level and helps ensure that only designated hosts assigned to that single storage port could access the specified RAID LUN; and (3) persistent binding, which forces a host to see a specific storage-subsystem port as a particular SCSI target and helps ensure that a specific storage-subsystem port on the SAN is always seen as the same SCSI target ID on the host, across the host and fabric, and throughout storage configuration changes. The advantages and disadvantages of these methods are described in Storage Area Network Security (2003).

The zoning security mechanism and access control are implemented at the switch level in the fabric. A port (either a host adapter or a storage controller port) can be configured as part of a zone. Only ports in a given zone can communicate with other ports in that zone. At the same time, the zoning mechanism also limits the traffic flow within a given SAN environment (Server Clusters 2003).

The fabric protection and management security technologies include: (1) fabric-to-fabric security technologies, which allow access control lists (ACLs) to permit or deny the addition of new switches to the fabric. The identity of the new switch may be validated by public key infrastructure (PKI) methods; (2) host-to-fabric security technologies, which apply ACLs at the port-level on the fabric, and permit or deny a particular host's FC HBA to attach to that port, and prevent an unauthorized intruder host from attaching to the fabric via any port; (3) management-to-fabric technologies, which use PKI and other encryption methods and ensure secure management in console-to-fabric communication; and (4) configuration integrity technologies, which ensure that propagated fabric configuration changes only come from one location at a time, and are correctly propagated to all switches on the SAN fabric with integrity. SAN security issues are discussed in Storage Area Network Security (2003) in detail.

SAN TECHNOLOGIES AND SOLUTIONS

The SAN infrastructures support multiple protocols, such as SCSI, simple network management protocol (SNMP), visual interface (VI), enterprise system connection/fiber connection (ESCON/FICON), TCP/IP, and session security

authentication and initialization protocol (SSAIP), over a single physical connection. This unique capability provides the SAN system with the coupled functionality of an interface to storage devices and a server interconnect.

In the early 1990s, fibre channel was developed by the Fibre Channel Systems Initiative (FCSI) and adopted later by the American National Standards Institute (ANSI) X3T11 Committee as a high-speed interface for connecting storage devices to servers and other network configurations. These interconnect standards (FC-PH 2001) provide SANs with the vital properties of connectivity, bandwidth, interconnectivity, protocol efficiency, distance range, recoverability, failure tolerance, and cost options. The fibre-channel standards specify electrical and optical transmission media as well as conventions for signaling and transmission/functional protocols. Optical media (with SC, LC, and mechanical transfer registered jack [MT-RJ] connectors) support reliable signaling over long distances. Fibre channel provides data rates in

the range from 133 Mbps to 4 Gbps over low-cost copper cabling (shielded twisted-pair wire or coaxial cable with serial communications d-shell connector, 9 pins [DB-9] and high-speed serial data connector [HSSDC]) or higher-cost multimode fiber-optic cable. Fibre-channel fabrics have transceivers, called “gigabit interface converters” (GBICs), which convert optical to electrical signals to cable connectors. Fibre-channel technology supports distances up to 10 km (see Table 2).

Optical and copper media are used in various SAN fibre-channel infrastructure applications (FCIA Roadmap 2006) including Inter Switch Links, SAN Edge Links, Back End Links, and Inter Device Links (see Table 3).

Fibre-channel Topologies

Fibre-channel methods have the means to implement three topologies: (1) point-to-point links, (2) shared bandwidth loop circuits known as fibre-channel arbitrated

Table 2: Maximum Distance for Fibre-channel Media Types

Data rate, MBps	12.5	25	50	100	200	400

loops (FC-ALs), and (3) bandwidth-switched fibre-channel fabrics (FC-SW) that provide SANs with the ability to do bandwidth multiplexing by supporting simultaneous data transmission between various pairs of devices. Any storage device on the loop can be accessed through a fibre-channel switch (FC-SW) or hub. The fibre-channel switch can support entry-level (8 to 16 ports) to enterprise-level (64 to 128 ports) systems. Under ANSI X3T11 standards, up to 126 storage devices (nodes) can be linked in the fibre-channel arbitrated loop (FC-AL) configuration, with the storage interface bandwidth about 100 Mbps for transferring large files. More than seventy companies, including industry-leading vendors of disk arrays and computer and networking systems, support the FC-AL voluntary standards. FC-AL topology is used primarily to connect disk arrays and FC devices. Originally developed as the high-speed serial technology of choice for server-storage connectivity, the FC-AL method is extended to the FC-SL standard that supports isochronous and time-deterministic services, including methods of managing loop operational parameters and quality-of-service (QoS) definitions, as well as control. The FC-VI regulation establishes a fibre channel-virtual interface architecture (FC-VIA) mapping standard. See *Fibre Channel* for more information about various implementations of the technology in various network configurations, including SANs.

Because of the high cost of the FC interconnect components and separation of storage and servers at the wide area network scale (resulting in slow capabilities of WAN-SANs with fibre channel), alternatives to FC technologies have been developed. The ipStorage technology (Barker and Massiglia 2001, 187) uses TCP/IP as a storage interconnect. The Internet Engineering Task Force (IETF) has proposed the iSCSI (Internet SCSI) standards (Hufferd 2002) that address the issues of long distances (WAN-scale), reducing the interconnect cost, high security, and complex storage network topologies. The iSCSI is layered on top of the TCP/IP protocol hierarchy and can instantly access all modern transmission media and topologies. TCP/IP and related protocols have been implemented in the server-based systems that allow the most general storage networks to be constructed with the iSCSI method (iSCSI and IP-SAN Solutions 2006). The main challenge is a reduction of the iSCSI processor overhead of operating iSCSI packets below the fibre-channel overhead level. See more details in *Storage Area Networks: Architectures and Protocols*.

InfiniBand Solutions

InfiniBand is a new emerging interconnect technology, developed by the standards of the InfiniBand Trade Association (founded by Compaq, Dell, Hewlett-Packard, IBM, Intel, Microsoft, and Sun Microsystems) that offers the most general low-cost server system topologies (InfiniBand Trade Association 2006). It is expected that InfiniBand interfaces will be embedded into all Intel-based servers (Barker and Massiglia 2001, 188–92; Intel InfiniBand Architecture 2006) and will allow Windows and Linux servers to be available for resolving complex problems of data centers by adopting clusters and

multiple-host enterprise RAID subsystems. InfiniBand technology implements a switched-fabric architecture with the packet-switching communication protocol (PSCP) that relates to the virtual interface (VI) architecture method. SANs, parallel processing systems, and systems area networks can effectively use InfiniBand as a high-performance/low-latency interconnect.

Crossroads Systems with a Storage Router

InfiniBand technology has been successfully implemented by Crossroads Systems, Inc., which promotes storage solutions based on protocol-independent connectivity at speeds of gigabit per second and unparalleled manageability for various storage devices. Crossroads' storage routers (e.g., Crossroads™ 10000) support peer operations between storage devices and multiprotocol servers on fibre-channel storage networks.

Brocade's Configurations

Brocade Communication Systems, Inc., has developed an intelligent fabric services architecture that creates a scalable and secure environment for enterprise mission-critical storage applications such as data backup and business continuity. The Brocade SANs (SilkWorm™ family of fabric switches and software) provide enterprises with any-server-to-any-storage-device connectivity and consolidate storage resources and servers, as well as sharing backup resources (Beauchamp, Judd, and Kuo 2002).

OTHER STORAGE NETWORKING TECHNOLOGIES

The following emerging technologies introduce new system architectural approaches in storage networking. SAN developers and users are trying to adapt them to a new enterprise environment that is characterized by host-level heterogeneous complexity, management flexibility, new TCP/IP network communication services, file-access-protocol developments, and the repartitioning of the functionality of file management systems.

VI (Virtual Interface) Architecture

The virtual interface (VI) architecture is a midlayer protocol specification that regulates virtual intercommunication between applications running on different remote servers (i.e., in a cluster). This method significantly reduces the latency and the volume of the system input/output (I/O) operations by using message and data buffer pools that are insensitive to the heterogeneous operating environment or other applications. The reduction of the I/O-related interrupts increases the CPUs' time for processing various other system tasks. Developers of the VIA technology (Compaq, Intel, Microsoft, etc.) use this architecture as an efficient way of message communication between the SAN nodes at the application level, creating only a small overhead of intercommunication between the remote applications. This method has been successfully implemented in database managers and NAS devices (Barker and Massiglia 2001, 189–90). Several efforts

(i.e., the direct access file system and network file system initiatives) have been made to improve file system performance by using VIA-type advanced transport protocol features. The Emulex Corporation promotes the GN9000/VI™ 1 Gbps VI/IP PCI host bus adapter, which is based on the virtual interface (version 1.0) architecture, supports standard TCP/IP-reliable data delivery, IP routing, and the direct access file system standard, and speeds data access over standard Gigabit Ethernet networks.

Direct Access File System

The direct access file system (DAFS) is a new file access/transfer protocol that is based on CIFS/NFS characteristics and VIA-type transport protocol features. DAFS/VIA technology supports direct file transfer between the storage system and clients. In a SAN environment, data can be directly transferred among a number of servers.

IP Storage Technologies

Another *block-mode data* mechanism has been used by the IETF IP Storage Working Group in developing standards for a new IP-based transport-through-network technology that encapsulates fibre-channel and SCSI high-speed interfaces and provides direct access to data on disks, tapes, and optical storage devices. IP storage technology allows embedding low-cost SANs into IP-based enterprise infrastructures over existing Gigabit Ethernet networks. See chapter on *Ethernet LANs*.

SANs over IP

To avoid the distance limitation of the fibre-channel interconnects, enterprises build remote SANs that can be interconnected by means of the SAN-over-IP technology originally developed by the Computer Network Technology Corporation. The distant SANs appear as local storage entities. This technology improves enterprise management and data access, disaster recovery, business continuity, disk mirroring, electronic tape vaulting, and wide area clustering. The Storage Networking Industry Association (SNIA) offers three technologies for integrating fibre-channel SANs into the IP backbone. These methods include fibre channel over IP (FCIP), Internet fibre channel over IP (iFCP), and Internet SCSI (iSCSI). The FCIP, iFCP, and iSCSI transport protocol descriptions are presented in Clark (2002).

Fibre channel over IP (FCIP)

FCIP is the simplest point-to-point IP tunneling solution for intercommunicating remote SANs with fibre-channel fabrics. The FCIP gateways establish TCP/IP connections over a WAN path to transport the fibre-channel encapsulated frames. A typical discrepancy in data communication rates between an FCIP-attached WAN link and fibre-channel fabric generates various flow control issues that can be resolved by TCP sliding-window algorithms. Several FC-FCIP management issues cannot be properly determined for the FCIP pipes because the TCP/IP transport component ends at the external nodes of the fibre-channel network. These problems have been

addressed and successfully resolved in the iFCP and iSCSI approaches.

Internet Fibre-channel Protocol (iFCP)

The gateway-to-gateway iFCP supports a means of integrating fibre-channel end devices into a single IP SAN. By using iFCP, the fibre-channel fabric services can be provided to the remote FC devices over a TCP/IP network. The iFCP IP storage switches can directly connect fibre-channel storage arrays, HBAs, hubs, switches, and routers. The iFCP is a protocol stack that can be implemented in an IP storage controller interface or integrated into Gigabit Ethernet IP storage network interface card (NIC) (known as ANSI X3T10 and X3T11 Standards) (Clark 2002, 126–39). It supports any-to-any IP routing of storage data. A mismatch in data communication rates between an iFCP-attached WAN link and fibre-channel fabric generates various flow-control issues that can be resolved by TCP sliding-window algorithms. The Internet protocol security (IPSec), public or private keys, and zoning methods can provide security across the Internet. One of the important applications of the iFCP technology is the support of multiple TCP/IP connections for concurrent storage transactions.

Internet SCSI (iSCSI)

In contrast to the FCIP concept, the iSCSI method, which follows the SCSI client/server model, is based on the implementation of a light-switch technology in IP storage networking (Clark 2002, 139–49) and excludes fibre-channel elements. The iSCSI servers (targets) are present in disk arrays and client nodes (initiators) that occupy host platforms. The iSCSI protocol over the TCP/IP layer is used for block data transport between these entities over the IP network. Data can be directly written into application memory through a steering and data synchronization layer located below the iSCSI sublayer. IPSec, Keyberos authentication, public key, and other methods can provide security across the Internet. SANs use the iSCSI adapters with TCP/IP offload engine (TOE) to minimize processing overhead and realize high-performance features of the iSCSI technology. The enterprise solutions with IP SANs can also support Gigabit and faster Ethernet on iSCSI-switch infrastructures (IP SAN Appliances 2006).

Storage over IP (SoIP)

Based on the SoIP remote storage technology, the Nishan Systems Corporation developed IP Storage switches of the IPS 4000 Series™ and a suite of storage management software that allows configuration and monitoring of large-scale storage networks.

Fabric Shortest Path First (FSPF)

FSPF is the open shortest path first (OSPF)-based standard routing protocol for fibre channel that determines the next shortest route for data traffic, updates the routing table, and detects the failed routes (Vacca 2002, 152). Optical, link, or switch failures can be effectively handled by FSPF with minimal impact on the interconnected devices in the FC/SAN environment.

Adaptive Network Storage Architecture (ANSA)

The Procom Technology Corporation has developed the ANSA approach, which delivers both block-level and file-level access to data. Procom's NetFORCE 3000™ Series provides filer functionality (together with advanced features of security, high stability, backup, and recovery) to enterprise storage that can result in high-performance information-management systems. The ANSA technology has been successfully applied to database management, data warehousing, e-mail delivering, and 24/7 rich-media applications.

Storage Resource Management (SRM)

The SRM technology provides applications for managing logical and physical storage-system resources (virtual devices, disk volumes, file resources, storage devices and elements, and appliances). SRM tools allow storage-system administrators to configure and monitor SANs and other storage resources. During the administrative monitoring, the transport or storage data remain unchanged. Vendors of the SRM tools, products, and services include SUN Microsystems (Sun StorEdge™), HighGround Systems, Inc. (Storage Resource Manager, Media Mirror), and Storage Computer Corp. (Storage Administrator) (Toigo 2001).

STANDARDS

American National Standards Institute (ANSI)

ANSI coordinates SAN voluntary standards (ANSI 2006). The ANSI X3T10 and X3T11 working committees are associated with storage networking issues, including SCSI I/O interface standards (X3T10) and fibre-channel interface standards (X3T11). The first set of fibre-channel standards (ANSI X.3230–1994) (Vacca 2002, 75–8) describes standards for a switch fabric (FC-SW2), the interconnect that supports high volumes of throughput and bandwidth for disk output and input, as well as a management information base (MIB) management standard that permits fibre-channel devices (switches) to be managed by any vendor's software, which includes an implementation of the simple network management protocol (SNMP). SAN users can find a brief description of other X3T11 fibre-channel standards in Barker and Massiglia (2001, 384–6).

Several FC SAN equipment vendors, including Brocade Communications Systems, have refined SAN standards in the areas of management, discovery, data transport, and WAN connectivity. This allows the fibre-channel SAN to become an integral part of the enterprise framework (Vacca 2002, 78–9).

Distributed Management Task Force (DMTF)

The DMTF has introduced management standards for computer systems and enterprise environment (DMTF 2006). The SAN-related management standards (Barker and Massiglia 2001, 386–7) cover a set of the Web-based enterprise management (WBEM) XML-based technologies. They support an object-oriented approach in developing

a business's management environment, using the Common Information Model; architectures and frameworks for desktop, laptop, and server management (desktop management interface); standard data models for a network, its elements, policies, and rules (directory-enabled networks); and functional calls for transaction monitoring (known as the application response measurement [ARM] standard).

Storage Systems Standards Working Group (SSSWG)

As a division of the Institute of Electrical and Electronics Engineers (IEEE), the SSSWG develops models and architectures of storage systems, including SANs (SSSWG 2006). The SSSWG project authorization requests (Barker and Massiglia 2001, 387–8) include the "Guide to Storage System Design"; media management system (MMS) architecture; session security, authentication, initialization protocol (SSAIP) of the MMS; media management protocol (MMP) for both client and administrative applications; drive management protocol (DMP) of the MMS; library management protocol (LMP) of the MMS; the media manager interchange protocol (MMIP) for information exchange between autonomous media managers; the media manager control interface protocol (MMCIP); the C language procedural interface for implementation of the MMS's components; MMS User mount commands for establishing "command line interfaces" (CLI); MMS standard administrative and operational commands for administering and operating an MMS; and "MOVER" specifications of a storage system data mover architecture and its interfaces.

Internet Engineering Task Force (IETF)

The IETF defines a variety of the transmission control protocol/Internet protocol (TCP/IP) standards that are widely used in the enterprise environment with SANs (IETF 2006). The IETF standards related to storage networking (Barker and Massiglia 2001, 388) include the simple network management protocol (SNMP) for managing and monitoring devices and systems in a network; the Internet protocol over fibre channel (IPoFC); and a policy for quality of services (QoS).

STORAGE NETWORKING ASSOCIATIONS, INITIATIVES, FORUMS, AND COALITIONS

The organizations discussed below promote storage networking technologies and products, develop standards, undertake marketing activities in information technology industry, educate, train, and create the knowledge base for implementing SAN technology:

SNIA (Storage Networking Industry Association)

The SNIA, an international association of developers of storage and networking products, is focusing on the creation of a forum of IT companies, system integrators,

and application vendors for delivering architectures, education, and services in storage networking, as well as defining the specifications and infrastructures, and proposing standards for storage networking systems, including SANs, SAN-attached storage (SAS), and network-attached storage (NAS) (SNIA 2006).

Fibre Channel Industry Association (FCIA)

The FCIA is an international organization of manufacturers, systems integrators, developers, systems vendors, industry professionals, and end users. In June 2002, this organization included more than 190 members and affiliates in the United States, Europe, and Japan. The FCIA is committed to delivering a broad base of fibre-channel infrastructure to support a wide array of industry applications within the mass storage and IT-based arenas. FCIA working groups focus on specific aspects of the technology that target markets, which include data storage networking and SAN management. The overview of fibre channel's SAN and networking applications and examples of fibre-channel solutions for high-performance networks of heterogeneous storage, server, and workstation resources can be found on the "technology" section of the FCIA Web site (FCIA 2006).

Fibre Alliance (FA)

The FA is the networking industry consortium originally founded by a group of storage networking companies, including EMC Corporation, to develop and implement standards for managing heterogeneous fibre-channel-based SANs. In collaboration with the IETF, this group develops the definition of simple network management protocol management information bases (SNMP MIB) for storage network and device management (Fibre Alliance 2006).

JIRO

Jiro is a Sun Microsystems technology that delivers intelligent management services for networked devices. Using the principles of Java and Jini platform-independent application development interfaces (Jini 2006), Jiro technology provides the architecture for connecting and managing complex distributed environments such as storage area networks. The Jiro technology brings higher levels of interoperability, adaptability, and manageability to enterprise networks with storage resources (Jiro 2002).

National Storage Industry Consortium (NSIC)

Since April 1991, the NSIC has consolidated the efforts of over fifty corporations, universities, and national labs in the field of digital information storage. The corporate members are major information storage manufacturers and companies from the storage industry infrastructure, including SANs. As a nonprofit organization, NSIC supports precompetitive joint research projects, involving collaboration among users and integrators of storage systems, storage system and device manufacturers, storage component and media manufacturers, suppliers, universities, and national laboratories (National Storage Industry Consortium 2006).

THE SAN MARKET, VENDORS, AND SERVICE PROVIDERS

Data storage management has become the primary issue for businesses in the past ten years. According to the International Data Corporation (IDC), the redundant array of independent disks (RAID) shipped in 2003 exceeded 250×10^{15} bytes (Storage Area Networks 2003). Data-rich businesses continue to seek effective data storage and management solutions to handle this data growth. SAN technologies allow existing enterprises to effectively manage more transactions, customers, suppliers, and services. Company operations are significantly improved by providing continuous high availability through uninterruptible access to data, increasing scalability through multiple-channel data transmission, and reducing the network and server's CPU overhead. Additional opportunities for the IT enterprises are also associated with the Internet, which allows them to increase the volume of data and rates of their transmission.

Evolution of the SAN Market

According to the Gartner's research study (Couture et al. 2006), the worldwide storage service market will grow from more than \$23 billion in 2004 to more than \$31 billion in 2009. The study conducted by the market research firm iSuppli Corporation (Gardner 2004) shows that the SAN enterprise market has been growing at an annual rate of 30% and promises to maintain that pace over the next five years. Among others, two growth factors will dominate: rapidly dropping prices on SAN solutions and better record-keeping practices mandated by federal legislation. By 2004, practically all large enterprises have installed SANs. Nowadays, SANs are being deployed by a growing number of mid-sized and smaller companies, including about 10% of enterprises with revenues of between \$100 million and \$300 million (Gardner 2004). Microsoft and other software providers have long viewed this market as a major growth opportunity, particularly for regulatory-compliant software packages that help protect confidentiality of patient records under the Health Insurance Portability and Accountability Act (HIPAA), which was introduced in April 2005 and requires the establishment of an IT infrastructure. Another factor of the future growing in the SAN installations is the Sarbanes-Oxley Act, which regulates how data are managed, archived, retrieved, and authenticated.

According to the Jupiter Media Metrix Corporation (Market Forecast Report 2002), the growth in Internet commerce is attributed to the increase in the U.S. online population by nearly 50%, from 141.5 million in 2001 to 210.8 million by 2006, as well as to the growth of U.S. online retail sales from \$47.8 billion in 2002 to an estimated \$130.3 billion in 2006. SANs have revolutionized the IT enterprise's infrastructure and improved its e-business applications, including e-commerce, e-mail, online transaction processing, data replication, and enterprise database management. Global continuous delivery of multimedia secured information has become the main service of modern e-business enterprises.

By adding networking and intelligence features to data storage, fibre-channel SAN switches enable the

solution of several challenging e-business storage problems, such as linking high-performance workstation clusters, connecting high-performance tape storage on disk farms, giving server farms a high-speed data-transmission pipe, clustering disk farms, and linking Ethernet, fiber distributed data interface (FDDI), asynchronous transfer mode (ATM), and token ring LANs to the backbone. Intelligent SAN systems allow improving enterprise performance significantly, decreasing latency, supporting direct access to the storage shared by multiple servers, reducing network traffic on the front-end network, and removing storage management tasks from servers.

A new SAN market is open for small to medium businesses (SMBs) that need flexible and scalable storage systems to ensure critical data that can be accessed quickly, securely, and cost effectively (Storage Management 2006).

According to New York-based market research firm Access Markets International (AMI) Partners Inc., SMBs in the United States spent \$443 million on SANs in 2003, and this figure is expected to grow to \$1.5 billion by 2008. Microsoft Corporation, together with business partners, has developed the Simple SAN Program that supports the iSCSI protocol, which allows SANs to be accessed over IP-based networks. New storage management capabilities have been built into Windows Server 2003 (Storage Management 2006).

SAN Vendors and Service Providers

Table 4 shows a list of SAN vendors, storage-networking service providers, and their products. The complete list of SAN deployment companies can be found in (Vacca 2002,

Table 4: SAN Vendors and Services

Company	Product Type	Source
ADVA Optical Storage Networking Technologies	Fiber Service Platform (FSP); DWDM system	(ADVA 2006)
ATTO Technology, Inc.	Fibre channel hub; Fibre channel, SCSI and IP storage solutions	(ATTO 2006)
Broadcom Corporation	SAN system core logic input/output chips	(Broadcom 2006)
Brocade Communication Systems, Inc.	Fabric switches; SAN solutions	(Brocade 2006)
Crossroads Systems, Inc.	Modular storage router	(Crossroads 2006)
Cutting Edge	Clustered failover; IP SAN solutions	(Cutting Edge 2006)
Dell Computer	Enterprise storage solutions; RAIDs	(Dell 2006)
EMC Corporation	Networked storage solutions	(EMC 2006)
Emulex Corporation	VI/IP PCI host bus adapters; SAN storage switchers	(Emulex 2006)
FalconStor Software, Inc.	Storage software; SAN infrastructure	(FalconStor 2006)
Fujitsu Ltd.	RAIDs	(Fujitsu 2006)
Hewlett-Packard	SAN management tools; storage systems	(Hewlett-Packard 2006)
Hitachi Data Systems/GST	SAN solutions	(Hitachi 2006)
IBM	Enterprise storage server; RAIDs; tape libraries; storage software	(IBM 2006)
Intel Corporation	iSCSI HBAs; GBICs; RAID controllers	(Intel Corporation 2006)
LSI Logic Storage Systems, Inc.	SAN solutions; RAID adapters	(LSI 2006)
McDATA	Enterprise FC management tools	(McDATA 2006)
Media Integration	Fibre channel SAN; iSCSI backup	(Media Integration 2006)
Microsoft Corporation	SAN management and backup software	(Microsoft 2006)
NEC Corporation	SAN support products	(NEC Corporation 2006)
Nishan Systems	IP storage switches	(Nishan Systems 2006)
QLogic Corp.	SAN management software; HBAs	(QLogic 2006)
SANRAD	iSCSI-SAN and IP-SAN solutions	(SANRAD 2006)
SUN Microsystems	Storage systems; RAIDs; disk backup	(Sun Microsystems 2006)
Unisys	SAN solutions	(Unisys 2006)
Xyratex	RAID systems	(Xyratex 2006)

Figure 2: Shares of leading companies in the SAN market. (Data source: Gardner 2004)

495–7) and on the Network Buyers Guide Web site (Network Buyers Guide 2006).

The iSuppli survey (Gardner 2004) identifies seven leading providers of SAN solutions: EMC (26% of all shares), Hewlett-Packard (25%), IBM (18%), Hitachi (8%), LSI Storage (7%), Sun Microsystems (7%), and Dell (6%) (see Figure 2). The additional information (based on the revenue analyses) about the top 10 largest storage companies for the period from 1999 to 2005 can be found in (Kerekes 2005).

CONCLUSION

SANs, networked high-speed infrastructures, enable e-business enterprises to significantly improve their 24/7 continuous scalable services. They have become a critical part of the enterprise network infrastructure. The above-considered technologies and effective SAN solutions allow companies to shift their focus from numerous IT infrastructure problems to the successful performance of their businesses and services.

GLOSSARY

CIFS: Common Internet file system, also known as the Microsoft server message block protocol; a network file system access protocol that is primarily used by Windows clients to communicate file access requests to Windows servers.

CIM: Common information model; an object-oriented description of entities and relationships in the enterprise management environment.

DWDM: Dense wavelength division multiplexing; a method that allows more wavelengths to use the same fiber.

FC-AL: Fibre channel-arbitrated loop transport protocol.

FCSW: Fibre-channel switch.

FC-VIA: Fibre channel-virtual interface architecture.

FSPF: Fabric shortest path first; a routing protocol used by fibre-channel switches.

High-availability cluster: Also known as failover cluster, this computer cluster is implemented for the purpose of improving the availability of services that the cluster provides. The cluster includes a redundant computer that is used to provide services when system components fail.

IPoFC: Internet protocol over fibre channel.

iSCSI: Internet small computer systems interface.

JBOD: Just a bunch of disks; a term for a collection of disks configured as an arbitrated loop segment in a single chassis.

LC Connector: A small form-factor fiber-optic connector, which resembles a small SC connector. Lucent Technologies developed the LC connector for use in telecommunication environments. The LC connector has been standardized as FOCIS 10 (Fiber Optic Connector Intermateability Standards) in EIA/TIA-604-10.

NAS: Network-attached storage.

RAID: Redundant arrays of inexpensive disks; a technology for managing multiple disks.

SAN: Storage area network.

SAS: SAN-attached storage.

SC Connector: A fiber-optic connector with a push-pull latching mechanism that provides for quick insertion and removal while also ensuring a positive connection. The SC connector has been standardized as FOCIS 3 (Fiber Optic Connector Intermateability Standards) in EIA/TIA-604-03.

SoIP: Storage over IP; a storage technology developed by the Nishan Systems Corporation.

SSA: Serial storage architecture.

VI: Virtual interface architecture; a midlayer protocol specification.

INTRODUCTION TO FIBRE CHANNEL

The small computer system interface (SCSI) has been used widely so far for connecting different storage devices to high-end computer systems to provide high-speed parallel data transmission. The devices can be daisy-chained together with a terminator at both ends of the SCSI cable. However, the SCSI has the following limitations: (1) the maximum length of a SCSI bus is 25 m; (2) the maximum number of devices a SCSI bus can connect is 32; and (3) the maximum transmission bandwidth of a SCSI bus is 80 MBps. As a result of the development of computer and multimedia technologies, a greater speed of data transmission among more devices over longer distances has been increasingly required. As a solution, a storage area network (SAN) can be used to connect with high-speed computers and storage devices. Two primary protocols for building SAN are fibre channel and SCSI over TCP/IP (also known as iSCSI [Hufferd 2003]).

The iSCSI protocol enables a SAN solution whereby SCSI is transported over the top of TCP/IP. iSCSI uses TCP/IP to establish sessions between iSCSI initiator and iSCSI targets. An iSCSI session may consist of multiple TCP connections. However, any given SCSI exchange must be conducted on one TCP connection. Because of the ubiquity of IP networks, iSCSI can be used to transmit data over local area networks (LANs), wide area networks (WANs), or the Internet and can enable location-independent data storage and retrieval. However, in this chapter, we will only discuss fibre channel.

Fibre channel (FC), a highly reliable, one or more gigabit (10 Gb in the near future) serial interconnect technology, allows concurrent communications among workstations, mainframes, servers, data storage systems, and other peripherals using SCSI, Internet protocol (IP) and a

wide range of other protocols to meet the needs of the data communication. Fibre channel was developed primarily to overcome the shortcomings of the current SCSI to provide higher speed and more scalable configuration. It turned out to be a technically attractive solution to the storage area network. Fibre channel can be used to implement SANs, to connect servers and high-performance workstations and mainframes, and to form the backbones between LANs. Currently, quite a number of manufactures provide various fibre-channel switches and end devices.

In order to help readers to understand fibre-channel technology, in the rest of the chapter, we will introduce fibre-channel protocol architecture, fibre-channel elements, fibre-channel transmission media and topologies, fibre-channel addressing, fibre-channel information transmission hierarchy, fibre-channel fabric routing, fibre-channel classes of service, fibre-channel flow control, mapping from other protocols to fibre channel, and fibre-channel distributed fabric services.

FIBRE-CHANNEL PROTOCOL ARCHITECTURE

Fibre channel is structured as a set of hierarchical functions. The American National Standards Institute (ANSI) FC-PI (fibre-channel physical interface) and ANSI FC-FS (fibre-channel framing and signaling) specifications define the fibre-channel layered-services model shown in Figure 1. As illustrated in Figure 1, the fibre-channel protocol consists of five layers: FC-0 (media and interface), FC-1 (transmission protocol), FC-2 (signaling protocol with link services), FC-3 (common services), and FC-4 (mapping from upper-layer protocols [ULPs] to fibre

Figure 1: Fibre-channel structure (SBCCS = single-byte command code set)

channel). Each layer of this model provides services to the layer above and relies on the services provided by the layer below.

A fibre-channel node is functionally configured as illustrated in Figure 2: A node may support one or more N_Ports and one or more FC-4s. Each N_Port contains FC-0, FC-1, and FC-2 functions. FC-3 optionally provides the common services to multiple N_Ports and FC-4s. (Thornburgh 1999)

The following describes the layers in Figure 1 and Figure 2 (Ogletree 2003):

- **FC-0:** The FC-0 layer specifies the link between two ports. This consists of a pair of either optical fiber or electrical cables with transmitter and receiver circuitry,

Figure 2: Node functional configuration

which work together to convert a stream of bits at one end of the link to a stream of bits at the other end. The FC-0 describes various kinds of media allowed, including single-mode and multi-mode optical fiber, as well as coaxial and twisted cables for shorter-distance links.

- **FC-1:** The FC-1 layer provides three primary functions: encoding and decoding data streams, managing ordered sets, and managing link-level protocols and states. The 8B/10B encoding scheme is used at FC-1 layer, which converts each 8-bit value into one of two possible 10-bit values. Each of the two 10-bit products of this conversion should have no more than six total 1's or 0's, about half will have an equal number of 1's and 0's. The 8B/10B encoding scheme can improve transmission characteristics on the link, and help receiver to recover clock, detect bit errors, and distinguish data bits from control bits. See the section below on 8B/10B Encoding.
- **FC-2:** The FC-2 layer is responsible for the functions associated with the establishment of communication between two ports. These functions include port login, the exchange, and associated frame sequences, flow control, and error control. The FC-2 layer also defined the fibre-channel frame format associated with all data and control frames. Link services defined in FC-2 are used to set up and manage links.
- **FC-3:** FC-3 (common services) provides a set of services that are common across multiple N_Ports and/or NL_Ports of a node. For example, services such as striping, hunt groups, and multicast are defined in FC-3. *Striping* is to multiply bandwidth using multiple N_ports in parallel to transmit a single information unit across multiple links. *Hunt groups* is the ability for more than one port to respond to the same alias address. This improves efficiency by decreasing the chance of reaching a busy N_Port. *Multicast* delivers a single transmission to multiple destination ports. This includes sending to all N_Ports on a fabric (broadcast) or to only a subset of the N_Ports on a fabric. FC-3 is under development.
- **FC-4:** The FC-4 layer defines how different higher-layer protocols are mapped to use fibre channel. The upper-layer protocols include intelligent peripheral interface (IPI), SCSI, high-performance parallel interface (HIPPI), IP, single-byte command code set (SBCCS) mapping, and others. Each of these protocols' commands, data,

and status are mapped into information units that are then carried by fibre channel.

FIBRE-CHANNEL ELEMENTS

The key elements of a fibre-channel network are the end systems and the network itself. The end systems are called “nodes”. A fibre-channel network consists of one or more switching elements. A switch is the smallest entity that may function as a switch-based fibre-channel fabric. A switch is composed of two or more switch ports; a switch construct, capable of either multiplexed frame switching or circuit switching, or both; an address manager; a path selector; a router; and a fabric controller. The collection of switching elements is called a “fabric.” The following types of fibre-channel ports are defined in the Fibre channel standards:

- **N_Port:** An N_Port exists in an end device that is connected to an N_Port on another end device to form a point-to-point topology or an F_Port on a switch to form a switched-fabric topology. Multiple N_Ports can exist in a single physical device.
- **NL_Port:** An NL_Port exists in an end device attached to an NL_Port of another end device or a fibre-channel hub to form an arbitrated-loop topology. NL_Port can also connect to an FL_Port on a switch to form a public-loop topology.
- **F_Port:** An F_Port exists in a switch that directly connects to the N_Port of an end device.
- **FL_Port:** An FL_Port exists in a switched-fabric that directly connects to the NL_Port of an end device to form a public arbitrated-loop topology.
- **E_Port:** An E_Port, expansion port, exists in a switch that connects to an E_Port of another switch to form an interswitch link (ISL). In other words, switches are connected to form switched fabric through E_Ports.
- **B_Port:** A B_Port, bridge port, exists in a switched fabric that extends a fibre-channel ISL over a non-fibre-channel port.
- **G_Port:** A G_Port is a switch port that is capable of either operating as an E_Port or F_Port. A G_Port determines through port initialization whether it operates as an E_Port or as an F_Port.
- **TL_Port:** A TL_Port is a translatable-loop port. It connects private loops to public loops or switches fabrics. A TL_Port acts as an address proxy for the private devices on the arbitrated loop.
- **GL_Port:** A GL_Port is a G_Port that is also capable of operating as an FL_Port.

Figure 3 illustrates how these types of ports can be used to connect switches and nodes to implement different possibilities (Cisco Systems 2004).

Figure 3: Fibre-channel connection modes

Figure 4: Fibre-channel variant nomenclature

FIBRE-CHANNEL TRANSMISSION MEDIA

The basic data rate over the fibre-channel link is just over 1 Gbps, with half-, quarter-, eighth-, double-, quadruple-speed and 10-Gbps links defined. The full-, double-, and quadruple-speed links are referred to as 1GFC, 2GFC, and 4GFC, which, respectively, provide a data-transmission bandwidth of about 100, 200, and 400 MBps. Using a different transmission code, the 10-Gbps link can provide about a 1200-MBps data-transmission bandwidth. To provide cost-effective fibre-channel migration, the Fibre Channel Industry Association (FCIA) introduced 8GFC, which provides about 800-MBps data-transmission bandwidth and full backward compatibility. Although the fibre-channel protocol is configured to match the transmission and technological characteristics of single- and multi-mode optical fibers, the physical medium used for transmission can also be copper twisted-pair, coaxial cable, or twin axial cable. For most of installations, the medium of choice is fiber-optic cable. Figure 4 illustrates the transmission speed, media, transmitter, and distance of fibre-channel technology (DeCusatis 2002). The fibre-channel standards define the maximum point-to-point transmission distance as 30 m for copper, and 10 km for optical fiber (www.t11.org). However, the maximum point-to-point link distance available in the market is reported to be 100 km (www.cisco.com). In the laboratory, the distance has reached 320 km while maintaining full throughput of the fibre channel at a 1-Gb line rate (www.cisco.com). Fibre-channel devices that support up to a 4-Gbps data rate are available in the market (www.cisco.com). Products with a bit rate of 8 or 10 Gbps are expected in the near future (www.fibrechannel.org).

FIBRE-CHANNEL TOPOLOGIES

Fibre channel is logically a bidirectional, point-to-point, serial data channel, structured for high-performance capability. A fibre-channel network may be implemented using any combination of the three topologies discussed below (Cisco Systems 2004) (Clark 2003).

Point-to-Point Topology

Point-to-point topology is used to directly connect two ports. As shown in Figure 5, the two fibre-channel-enabled devices, D1 and D2, are directly connected through two N_Ports without using any switch. The transmission between the two devices in the point-to-point topology is full-duplex, therefore point-to-point topology can be seen as a two-node loop topology.

Arbitrated-Loop Topology

Similar to token ring, arbitrated-loop topology is used to connected devices, each connected to two others by unidirectional transmission links to form a single closed path. As shown in Figure 6, the NL_Port of three end devices, D1, D2, and D3, are connected to form a unidirectional loop. Up to 127 nodes, including one possible hub port, can be supported in this topology. The loop is

Figure 5: Point-to-point topology

Figure 6: Arbitrated-loop topology

generally implemented using a fibre-channel hub for cable management.

Switched-Fabric Topology

Switched-fabric topology is the most general topology supported by fibre channel. At least one fibre-channel switch is needed in this topology, as shown in Figure 7. The “fabric” in Figure 7 can be one switch or multiple switches connected by interswitch links.

In applications, the three primary topologies (point-to-point, loop, and switched-fabric) can be connected to form a complex topology. For example, using a switch to connect multiple arbitrated loops allows one to bypass the 126-node limit that is inherent in using the single arbitrated-loop topology. Although each loop attached to a switch is still limited to 126 nodes, the switch makes a connection between these loops so that devices can communicate with each other, no matter which loop each device is connected to. One can also link multiple switches that have arbitrated loops attached. See Figure 3 for a more complex network topology that consists of point-to-point topology, arbitrated-loop topology, and switched-fabric topology.

Figure 7: Switched-fabric topology

FIBRE-CHANNEL ADDRESSING

Fibre channel has two types of addresses that are used to identify a device or switch port. The first is a globally unique assigned address called the worldwide name (WWN). The WWN is assigned by the manufacturer and is guaranteed to be globally unique.

The second type of address used in fibre channel is a dynamically assigned hierarchical address that lets frames be intelligently routed from one device to another. That is (called the “fibre-channel ID” [FC_ID]), the dynamic address contains information about where the device is connected to. In fibre-channel networks, the FC_ID is mapped to the WWN such that initiators can use the WWN to contact a device, and it will be translated to an FC_ID for communication.

The FC_ID addresses assigned to devices depend on the type of topology:

Point-to-Point: Point-to-point connections are actually implemented as a private loop with two devices. Because the devices are in a private loop, they use only an 8-bit arbitrated-loop physical address (AL_PA). The address is in the range of 0x000001h to 0x0000EFh.

Private Arbitrated Loop: Arbitrated loops can be implemented as private or public loops that determine the type of addresses assigned. In a private-loop topology, a standard AL_PA is assigned in a fashion similar to that of point-to-point topology. Each device on a private loop is assigned an address in the range of 0x000001h to 0x0000EFh (however only 126 devices may exist in a given arbitrated loop because of the 8B/10B encoding).

Public Arbitrated Loop: A public loop contains one or more FL_Ports that act as gateways to a switched fabric. As such, the addresses assigned to devices on a public loop contain a full 24-bit address. The first byte is the Domain_ID that is assigned to the switch. The second byte identifies the particular loop on the switch. The third byte is used for the AL_PA assigned to the devices on the loops. The FL_Port always has an AL_PA of 0x00h. Therefore, the valid FC_ID address range for devices on a public arbitrated loop are 0xdd11aa 0 (Cisco Systems 2004) where dd is the Domain_ID of the attached switch in the range of 0x01h to 0xEFh (1 to 239), 11 is the loop identifier in the range of 0x00h to 0xFFh, and aa is the AL_PA in the

Table 1: Fibre channel Addressing

	8 bits	8 bits	8bits
Switch topology	Domain (01-EF)	Area (00-FF)	Device (00-FF)
Private loop topology	00	00	AL_PA (01-EF)
Public loop topology	Domain (01-EF)	Area (00-FF)	AL_PA (01-EF)

range of 0x01h to 0xEFh, where 0x00h is reserved for the FL_Port. It is apparent that the format of the FC_ID, 0xdd11aa, can be used for facilitating routing in a way similar to netmask-based routing in IP.

Switched Fabric: A switched fabric address is based on FC_IDs that use the entire 24-bit address. Each switch within a switched fabric is assigned one or more Domain_IDs. This Domain_ID can be thought of as a routing prefix that the switch uses to route frames to devices connected to other switches. The first byte of a switched fabric FC_ID is the Domain_ID. It is in the range of 0x01h to 0xEFh. The second and third byte of a switched fabric FC_ID are called the Area_ID and Port_ID, respectively.

Table 1 gives the addressing ranges for the three different topologies.

FIBRE-CHANNEL INFORMATION TRANSMISSION HIERARCHY

The signaling-protocol (FC-2) level serves as the transport mechanism of fibre channel. To aid in the transport of data across the link, the following building blocks are defined by the FC-2 standard: ordered set, frame, sequence, and exchange. Figure 8 shows the relationship between frames, sequences, and exchanges. An exchange consists of one or more sequences, while a sequence in turn consists of one or more frames. A frame uses ordered sets to delimit its start and end. An ordered set consists of four 8B/10B encoded transmission characters. In the following, we will introduce the 8B/10B encoding, ordered set, frame, sequence, and exchange.

**Figure 8:** Relationship between frames, sequences, and exchanges

Order of bits to be encoded	b_7	b_6	b_5	b_4	b_3	b_2	b_1	b_0	
8B/10B unencoded bit notation	H	G	F	E	D	C	B	A	
Zxx.y notation	Z	E	D	C	B	A	H	G	F
	xx					y			

Figure 9: Zxx.y notation

8B/10B Encoding

At FC-1 layer, information to be transmitted over a fibre channel is encoded 8 bits at a time into a 10-bit transmission character using the 8B/10B encoding scheme and then sent serially bit by bit across the link. Information received over the link is collected 10 bits at a time. The transmission characters that are used for data, called “data characters,” are decoded into the correct 8-bit codes.

The 8B/10B encoding starts off with a process of assigning a letter to each bit in a single byte to be transmitted. As shown in Figure 9, letters H, G, F, E, D, C, B, and A are assigned to bits b_7 , b_6 , b_5 , b_4 , b_3 , b_2 , b_1 , and b_0 of the byte to encode, respectively. Then Zxx.y notation is formed by calculating the decimal value xx using the lower 5 bits of the byte (letters EDCBA) and calculating decimal value y using the higher 3 bits of the byte (letters HGF). In other words:

$$xx = b_4 \times 2^4 + b_3 \times 2^3 + b_2 \times 2^2 + b_1 \times 2 + b_0$$

while

$$y = b_7 \times 2^2 + b_6 \times 2 + b_5$$

Let the letter K signify a special character and the letter D signify a data character. Then Kxx.y and Dxx.y represent a special character and a data character, respectively.

Refer to Figure 10, as an example, take 0xBCh as the byte to encode: the corresponding Zxx.y notation is Z28.5, the data character is D28.5, and the special character is K28.5. Each transmission character (data or control) can have one of two possible binary values. By looking up the encoding table, K28.5 has two possible 10-bit

Order of bits to be encoded	b_7	b_6	b_5	b_4	b_3	b_2	b_1	b_0
	1	0	1	1	1	1	0	0
8B/10B unencoded bit notation	H	G	F	E	D	C	B	A
	1	0	1	1	1	1	0	0
Zxxx.y notation	Z	E	D	C	B	A	H	G
	K	1	1	1	0	0	1	0
	28					5		

Figure 10: Translation of K.28.5

values: 0011111010 (positive parity) and 1100000101 (negative parity). Which of the two possible binary values is transmitted depends on the disparity of the previously transmitted character. If a positive disparity character is transmitted, the next character issues should have negative parity. By monitoring the running disparity of the preceding event, the encoder can ensure that an overall balance of 1's and 0's is maintained in the serial stream.

The 10-bit transmission code supports all 256 eight-bit combinations. 12 of the remaining transmission characters, referred to as "special characters," are defined by the 8B/10B encoding scheme. However, only the K.28.5 character is used in fibre channel, which is distinguishable from the contents of a frame and therefore can assist a receiver in achieving word alignment on the incoming bit stream.

The primary rationale for use of a transmission code is to improve the transmission characteristics of information to be transferred across a fibre channel. The encodings defined by the transmission code ensure that sufficient transitions are present in the serial bit stream to make clock recovery possible at the receiver. Such encoding also greatly increases the likelihood of detecting any single- or multiple-bit errors that may occur during transmission and reception of information.

Ordered Set

Ordered sets are a very important mechanism used in fibre-channel communications, and are used for many different purposes. An ordered set consists of four encoded bytes, which means 40 bits, because each byte is encoded into 10 bits by using 8B/10B encoding. Ordered sets can be classified into three basic categories:

- *Start of frame and end of frame delimiters:* Refer to Figure 11, one ordered set (SOF) is used to indicate the start of a frame, while another (EOF) is used to indicate the end of a frame. There are several different SOFs and EOFs defined in the fibre-channel standards. These SOF delimiters are also used to define the class of service to be used and whether the frame is the first in a series of frames. Like SOF, EOF can also be used to convey some other information about the frame.

- *Primitive signals:* The primitive signals are used for various purposes to initiate certain events on the transport medium. For example, when the medium is not being used, IDLEs signals are generated. Another type of primitive signal is the R_RDY (receive ready), which is used in buffer-to-buffer credit operations.
- *Primitive sequences:* The primitive sequences are used to control state changes on the fibre-channel link, such as initialization and recovery. An example of a primitive sequence is the set of LIP (loop initialization primitive) sequences used to initialize an arbitrated loop.

Frame

FC-2 framing protocol manages flow control so that data will be delivered with no collision or loss. This level defines the signaling protocol, including the frame and byte structure, which is the data-transport mechanism used by fibre channel. Frames transfer all information between nodes. The frames are normally constructed by the transmitting node's N_Port. A frame is the smallest unit of information transfer across a link. The format of a fibre-channel frame is shown in Figure 11.

It can be seen in Figure 11 that the size of a fibre-channel frame can be from 36 bytes to 2148 bytes, depending on the size of the data filed. IDLEs are used for synchronization and word alignment between transmitter and receiver. IDLEs indicate the readiness to transmit and are constantly transmitted when no other data are presented to send. An IDLE is actually a 4-byte ordered set. After the 4-byte SOF is the 24 byte frame header. The frame header includes fields such as the source FC_ID, destination FC_ID, and other necessary parameters. The data field consists of the actual upper-layer protocol data, which can range from 0 to 2112 bytes. Calculated using the frame header and the data field, the 4-byte cyclic redundancy check (CRC) code is used to check the correctness of the frame. The CRC used in fibre channel is a 32-bit polynomial:

$$x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$$

As shown in Figure 12, the 24-byte frame header is used to indicate the source and destination address of the

IDLEs	SOF	Frame Header	Data Field	CRC	EOF	IDLEs
4 bytes	4 bytes	24 bytes	0-2112 bytes	4 bytes	4 bytes	

Figure 11: Fibre-channel frame format

Figure 12: Fibre-channel frame header format

Table 2: Fields in Fibre channel Frame Header and Their Descriptions

Field	Length (bytes)	Description
R_CTL	1	Routing control contains routing bits and information bits to categorize the frame function. Routing bits differentiate frames based on function or service, such as data frames versus link control frames containing commands or status.
D_ID	3	Destination fibre-channel ID.
CS_CTL	1	Class-specific control contains management information for the class of service identified by the SOF. The meaning of the CS_CTL field is dependent on the class of service.
S_ID	3	Source fibre-channel ID.
Type	1	Type indicates the upper-level protocol carried in the frame payload, such as IP (TYPE is equal to 0x05h) and SCSI (TYPE is equal to 0x0Ah–0x0Fh).
F_CTL	3	Frame control contains a number of flags that control the flow of the sequence.
SEQ_ID	1	Sequence identifier uniquely identifies a given sequence within an exchange.
DF_CTL	1	Data field specifies the presence of optional headers at the beginning of the data field.
SEQ_CNT	2	Sequence count identifies the order of the transmission of frames within a sequence. It is used by a sequence recipient to account for all transmitted frames.
OX_ID	2	Originator exchange identifies an individual exchange. This identity is set by the originator of exchange.
RX_ID	2	Responder exchange identifies an individual exchange. This identity is set by the responder to exchange.
Parameters	4	The parameters field is dependent on the frame type, as identified in the R_CTL field.

frame, and also contains fields that are used to describe the content of frame. Table 2 describes briefly each field in the fibre-channel header.

Sequences and Exchanges

An exchange, unidirectional or bidirectional, is the fundamental mechanism for coordinating the interchange of information and data between two Nx_Ports. All data transmission is part of an exchange. An exchange is a set of one or more interrelated sequences, each of which flows unidirectionally between a pair of Nx_Ports. Within

a single exchange, only one sequence will be active at any given time for a single initiating Nx_Port. A sequence is a data transmission that can contain one or more frames. The framing protocol is used to break sequences into individual frames for transmission, flow control, CRC generation, and various classes of service. As illustrated by Figure 8, by using the concept of an exchange, much of the overhead of setting up a connection—or terminating the connection—between two devices is made much simpler. To enable each of the communicating devices to distinguish between multiple sequences, a sequence ID is used. To keep track of exchange, an exchange ID is used.

Thus, for two devices communicating on a fibre-channel network, multiple transmissions of data (sequences) can be in process at the same time, contained within a single exchange.

Each frame is verified for validity during reception. The error recovery is done on the basis of sequence. Thus, if an error is detected with a sequence, then the entire sequence is retransmitted, without affecting other sequences in an exchange that are made up of multiple sequences. For classes of service that require an acknowledgment, the transmitter retransmits the sequence after a timer has expired, assuming that the sequence was not received intact.

FIBRE-CHANNEL FABRIC ROUTING

Routing is not needed for point-to-point topology and arbitrated-loop topology, since there exists only one possible route between any two devices.

In a switched-fabric topology, a dynamic routing protocol, called fabric shortest path first (FSPF), is used to route frames through the connected fabric. The FSPF is based on the widely used TCP/IP dynamic routing protocol open shortest path first (OSPF). The FSPF is a link-state protocol that requires all switches to exchange link-state information, including the operational state and routing metric for each direct ISL. The topology database is central to the operation of FSPF. It is a replicated database in which all switches in the fabric have the same exact copy of database at all times. Using this information stored in the local database, each switch performs the Dijkstra algorithm to compute the shortest path to every other Domain_ID, and then to build its own routing table. FSPF performs hop-by-hop routing, meaning that a switch only needs to know the next hop on the best path to the destination. A routing table entry minimally consists of a destination Domain_ID, and an E_Port to which frames are forwarded to the destination switch.

The FSPF has four major components:

1. A Hello protocol, used to establish connectivity with a neighbor switch, to establish the identity of the neighbor switch, and to exchange FSPF parameters and capabilities
2. A replicated topology database, with the protocols and mechanisms to keep the databases synchronized across the fabric
3. A path computation algorithm (with Dijkstra's algorithm being a possible candidate)
4. A routing table update (which is straightforward once the shortest path tree is generated)

The topology database synchronization in turn consists of two major components: an initial database synchronization and an update mechanism. The initial database synchronization is used when a switch is initialized, or when an ISL comes up. Reliable flooding is the mechanism by which topology changes are propagated throughout the fabric. Reliable flooding is used whenever any change of a switch link state occurs, but is not used for the initial database synchronization when an ISL between two switches initializes.

FIBRE-CHANNEL MEDIA ACCESS CONTROL

Fibre channel supports any combination of three primary topologies: point-to-point, arbitrated-loop, and switched fabric. Fibre channel uses a connection method that requires the setup of a channel between two devices before any data are exchanged. However, several steps must occur to establish a channel. After the channel has been established, communication between two end devices occurs according to a hierarchical model (see the section on Fibre-channel Information Transmission Hierarchy above). The following steps are required to establish communication between two devices using the different fibre-channel topologies discussed below.

Point-to-Point

Point-to-point topology is treated as an arbitrated-loop topology with two nodes in fibre channel. Devices connected point-to-point must first perform a loop initialization procedure (LIP) to determine that they are in a point-to-point configuration rather than an arbitrated-loop.

Arbitrated Loop

For arbitrated-loop topology, arbitration is used instead of a token that is used in Institute of Electrical and Electronics Engineers (IEEE) 802.5 protocol. Each device has a certain priority, based on its address. To gain access to the network, a device must "arbitrate" for it. If a loop is connected to a fabric switch port, then the FL_Port has the highest priority since it has the lowest AL_PA address (0x00h). Therefore, it can always win the arbitration and gain access to the loop when it needs to send frames.

Other devices must contend for loop access. They issue the arbitrate primitive, called ARB(x), where x is the port address of the requestor on the network. IDLE primitive sequence circles the loop after the initialization process. When one or more nodes on the network send out an arbitration frame, a comparison is made by the nodes based on the priority of the ARB(x) frame received. If a node wanting to transmit data at the same time receives an ARB(x) frame that has lower priority than its own, then it simply discards that frame and does not retransmit it to the next node on the loop. Instead, the node sends out its own arbitration frame so that any other node issuing ARB(x) frames will know that it has won the arbitration process. Then the winner of the arbitration process receives the frame that it sent out, it knows it is the winner (because no other device wanting to transmit has a higher priority), and the node then transmits data frames on the loop.

When a member of the loop receives its own arbitration frame, it can then send an open frame onto the loop informing other nodes that it has arbitrated for access and wants to open a communication link with a specific target node.

The arbitration process allows for a fair access mechanism so that even devices with a low priority can eventually gain access to the loop. This is dependent on implementation. As far as the sender and receiver are

concerned, they are now in a point-to-point connection, though the frames may be traveling through other nodes on the loop that are in the monitoring state, simply forwarding the frames. However, in most cases, the sender also monitors other frames traveling the loop and can tell if another node is trying to gain access to the loop. Although there is no specified number of frames the sender and the receiver can exchange, most devices try not to take a long time. Instead, most devices play in a fair manner and, after transmitting a number of frames, release their exclusive access to the loop to allow other members to make use of the shared media.

Switched Fabric

In switched-fabric topology, a dedicated connection between two connected ports is provided by switched fabric. Since bandwidth is not shared between ports, all ports can perform at full bidirectional speed for transmitting and receiving at all times.

FIBRE-CHANNEL CLASSES OF SERVICE

Fibre channel defines several classes of service. Each class of service is differentiated by its use of acknowledgment, flow control (refer to the section on Fibre-channel Flow Control below), and channel reservation:

- Class 1 is a connection-oriented service with confirmation of delivery or notification of nondelivery. A dedicated channel must be established from source to destination before the connection is granted. Once established, the two N_Ports can communicate using the full bandwidth of the connection, and no other traffic affects this communication. All the frames will follow the same connection. Because of this nature, frames are guaranteed to arrive in the order they were transmitted. Also, the media speeds must be the same for all links along the dedicated connection. There is no need for buffer-to-buffer flow control. Therefore, only end-to-end flow control is used in class 1 (see the section on Fibre-channel Flow Control below).
- Class 2 is a connectionless service between ports with confirmation of delivery or notification of nondelivery. A connectionless service does not need connection established. Instead, different frames may be sent through different paths depending on the present situation of the switched fabric. A port can transmit frames to and receive frames from more than one N_Port. As a result, the N_Ports share the bandwidth of the links with other network traffic. Multiplex may be involved in class 2 service. Frames are not guaranteed to arrive in the order they were transmitted, except for the point-to-point or loop topologies. In addition, the media speeds may vary for different links that make up the path. Both buffer-to-buffer and end-to-end flow control are used in class 2 (see the section on Fibre-channel Flow Control below).
- Class 3 is a connectionless service between ports with no confirmation of delivery or notification of nondelivery. Class 3 is very similar to class 2 except that it only uses buffer-to-buffer flow control (see the section on Fibre-channel Flow Control below).
- Class 4 provides fractional bandwidth allocation of resources of a path through a fabric that connects two N_Ports. This connection-oriented service provides a virtual circuit between N_Ports with confirmation of delivery or notification of nondelivery and guaranteed bandwidth. One N_Port will set up a virtual circuit by sending a request to the fabric indicating the remote N_Port as well as quality-of-service parameters. The resulting class 4 circuit will consist of two unidirectional virtual circuits between the two N_Ports. The virtual circuits need not have the same speed.
- Class 6 is a multicast variant of class 1 providing one-to-many service with confirmation of delivery or notification of nondelivery and guaranteed bandwidth. A device wanting to transmit frames to more than one N_Port at a time sets up a class 1 dedicated connection with the multicast server within the fabric at the well-known address of 0xFFFF5h. The multicast server sets up individual dedicated connections between the original N_Port and the entire destination N_Ports. The multicast server is responsible for replicating and forwarding the frames to all other N_Ports in the multicast group. N_Ports become a member of a multicast group by registering with the alias server at the well-known address of 0xFFFF8h.
- Intermix is an option of class 1 in which class 2 and class 3 frames may be transmitted at times when class 1 frames are not being transmitted.

FIBRE-CHANNEL FLOW CONTROL

Flow control is to ensure that the buffer of the recipient will not be overwhelmed by the initiator. Fibre-channel flow control is based on a permission system in which a device or port cannot transmit a frame unless it has a credit. Fibre channel has two flow control mechanisms—end-to-end and buffer-to-buffer.

End-to-end flow control is used to pace traffic between two end devices and can be used in class 1 and class 2 service. The end-to-end mechanism means that the intervening switches do not have to participate in the credit/acknowledgment scheme. Instead, when a connection is being set up between the initiator and the target device, the value used for the credit system is decided. This is usually based on the amount of buffer space that the recipient has installed on the adapter. When a frame is transmitted by an initiator, it subtracts one from the number of credits it has been granted. When an acknowledgment is received from the target device, the value of the credits is increased by one. This simple mechanism allows both ends of the connection to maintain a steady flow of data without overwhelming the recipient.

Buffer-to-buffer flow control takes place between every adjacent pair of ports along any given path in a fibre-channel network or between two devices on an arbitrated loop. Buffer credits relate to the number of input buffers that exist on the connected port. During a fabric login procedure, the number of buffer credits available to adjacent devices is exchanged. When an input buffer is

emptied, a device generates a 4-byte R_RDY command and sends it to the neighboring feeder device, thereby incrementing the credit. The buffer-to-buffer flow control algorithm used in fibre channel is simpler than the sliding windows used in TCP/IP.

MAPPING OTHER PROTOCOLS TO FIBRE CHANNEL

Mapping is a set of rules that is defined to move information from ULP interfaces to the lower fibre-channel levels. The ULPs include IPI, SCSI, HIPPI, IP, SBCCS, and others. Each of these protocols' commands, data, and status are mapped into information units that are then carried by fibre channel. In the following, only IP over fibre channel and SCSI over fibre channel are introduced.

IP over Fibre channel

Establishing of IP communications with a remote node over fibre channel is accomplished by establishing an exchange. Each exchange established for IP is unidirectional. If two nodes wish to interchange IP datagrams, a separate exchange must be established for each direction. A set of IP datagrams to be transmitted is handled at the fibre channel as a sequence.

An address resolution protocol (ARP) server must be implemented to provide mapping between 4-byte IP addresses and 3-byte fibre-channel IDs. Generally, this ARP server will be implemented at the fabric level at the address of 0xFFFFFCh.

SCSI over Fibre channel

The fibre channel acts as a data-transport mechanism for transmitting control blocks and data blocks in the SCSI format. A fibre-channel N_Port can operate as a SCSI source and target, generating or accepting and servicing SCSI commands received over the fibre-channel link. The fibre-channel fabric topology is more flexible than the SCSI bus topology, since multiple operations can occur simultaneously.

Each SCSI operation is mapped over the fibre channel as a bidirectional exchange. A SCSI operation requires several sequences. A read command, for example, requires: (1) a command from the source to the target, (2) possibly a message from the target to the source indicating that it is ready for the transfer, (3) a "data phase" set of data flowing from the target to the source, and (4) a status sequence, indicating the completion status of the command. Under fibre channel, each of these messages of the SCSI operation is a sequence of the bidirectional exchange.

FIBRE-CHANNEL DISTRIBUTED SERVICES

A distributed-services model in fibre channel is used to allow a switched fabric to provide consistent services to all attached N_Ports, to aid in the management, configuration, and security of a fibre-channel fabric. The following introduces fabric log-in, directory services, zone services,

management services, and state change notification services.

Fabric Log-in

Fibre channel defines two types of log-in procedures: fabric and N_Port. With the exception of private NL_Ports, all other node ports must attempt to log in with the fabric. This is done after the link or the loop has been initialized. A fabric log-in starts by sending a fabric log-in (FLOGI) frame to the well-known fabric address of 0xFFFFFEh. The following things can be accomplished through port log-in:

- It determines the presence or absence of a fabric.
- If a fabric is present, it provides a specific set of operating characteristics associated with the entire fabric, including which classes of service are supported.
- If a fabric is present, the N_Port that initiated the login can receive a fibre-channel address (FC_ID).
- If a fabric is present, it initializes the buffer-to-buffer credit.

Before an N_Port communicates with another N_Port, it must first log in to that N_Port. The port log-in (PLOGI) procedure can accomplish the following things:

- It provides a specific set of operating characteristics associated with the destination N_Port, including which classes of service are supported.
- It initializes the destination end-to-end credit.
- In a point-to-point topology, it initializes the buffer-to-buffer credit.

Both fabric log-in and N_Port log-in are intended to be long-lived. Once logged in, a device can stay logged in indefinitely, even if it has no further data to transmit at that time.

Directory Services

A fibre-channel switched fabric supports a distributed directory service called "name server." Since the FC_ID assigned in a fibre-channel fabric is dynamic, a service that can map a device's static WWN to its routable FC_ID is necessary. The name server is accessed by performing a port log-in (PLOGI) to a well-known address of 0xFFFFFCh.

Zone Services

A fibre-channel fabric provides zone services to restrict communication between attached devices. A fibre-channel zone is a logical grouping of devices that are permitted to communicate. Because these devices may be attached to different switches, the zoning configuration is distributed between all switches in the fabric.

Management Services

The management service lets device attributes and configuration information be retrieved within the fabric.

This information may include attributes such as software versions, hardware versions, device capabilities, logical device names, and device-management IP addresses.

State-Change Notification Services

Because fabrics are a dynamic environment and may undergo topology changes when new devices are attached or previously active devices are taken off, it is useful if notification of changes can be provided to other participants. When events occur in the network, either accidentally or intentionally, registered state-change notifications (RSCNs) are generated to notify other devices of the event occurrence. Using the RSCN facility, devices can react much more quickly to failure events rather than waiting for timers to expire. RSCN is a voluntary function in that an N_Port or NL_Port must register its interest in being notified of network changes if another device alters state.

CONCLUSION

Fibre channel is backed by an industry group known as the Fibre Channel Association, and a variety of interface cards, storage devices, and switches for different applications are available. Being the major force for SANs, fibre channel has been most widely accepted as an improved peripheral device interconnection. It is a technically attractive solution to general high-speed LAN requirements but must compete with Gigabit Ethernet and asynchronous transfer mode (ATM) LAN. For implementing storage network, fibre channel will have to compete with iSCSI (internet SCSI) that uses TCP/IP to establish SCSI sessions across a long distance (Stallings 2004).

GLOSSARY

8B/10B Encoding: 8B/10B is a line code used in fibre channel, which maps 8-bit symbols to 10-bit symbols to achieve DC (direct current) balance and bounded disparity, and yet provide enough state changes to allow reasonable clock recovery.

Arbitrated Loop: A fibre-channel interconnection topology in which each port is connected to the next, forming a loop. At any instant, only one port in a fibre-channel arbitrated loop can transmit data. Before transmitting data, a port in an arbitrated loop must participate with all other ports in the loop in an arbitration to gain the right to transmit data.

Exchange: An exchange is a set of one or more nonconcurrent related sequences passing between a pair of fibre-channel ports. An exchange encapsulates a "conversation" such as SCSI task or an IP exchange. An exchange may be bidirectional.

Fibre Channel: Fibre channel is a gigabit enabling technology for SANs. An industry standard storage/networking interface, it connects host systems, storage devices, and others by means of a point-to-point bidirectional serial interface.

Frame: A frame, the basic unit of transmission on a network, is a collection of bits that contain both control information and data. A fibre-channel frame begins with a 4-bytes start of frame (SOF), ends with a 4-bytes end of frame (EOF), includes a 24-byte frame header and 4-byte Cyclic redundancy check (CRC), and can carry a variable data payload from 0 to 2112 bytes, the first 64 of which can be used for optional header.

iSCSI: iSCSI is Internet SCSI (also known as SCSI over TCP/IP), an Internet protocol (IP)-based storage networking standard for linking data storage facilities. By carrying SCSI commands over IP networks, iSCSI is used to facilitate data transfers over intranets and to manage storage over long distances.

Port: The hardware entity that connects a device to a fibre-channel topology. A device can contain one or more ports.

Private Loop: A fibre-channel arbitrated loop with no attachment to a switched fabric.

Public Loop: A fibre-channel arbitrated loop with an attachment to a switched fabric.

SCSI: Abbreviations for small computer system interface. It is a fast parallel bus structure for connecting a computer to peripheral devices such as disk drives, tape drives, CD-ROM drives, and printers.

Sequence: A sequence is a set of fibre-channel data frames with a common sequence ID, corresponding to one message element. Sequences are transmitted unidirectionally from initiator to recipient, with an acknowledgment transmitted from recipient to initiator.

Storage Area Network: A storage area network (SAN) is a high-speed dedicated network designed to connect computer storage devices to servers.

Switched Fabric: Switched fabric is a set of one or more fibre-channel switches interconnected by interswitch links (ISLs). Data can be transmitted physically between any two ports on any of the switches.

INTRODUCTION

The rapid growth of data-intensive applications, such as multimedia, e-business, e-learning, and Internet protocol television (IPTV), is driving the demand for higher data-storage capacity. Companies and organizations want their data to be stored in such a way that the huge amount of data can be easily accessible and manageable. Furthermore, they also require the critical data to be securely transported, stored, and consolidated at high speeds (Ching 2000). Traditionally, on client/server systems, data are stored on devices either inside or directly attached to the server; this is thus known as direct attached storage (DAS). Next in the evolutionary scale comes network attached storage (NAS), which takes the storage devices away from the server and connects them directly to the network. Recently, storage area networks (SANs) push the network storage technology further by connecting storage devices into a separate network and allowing them to directly communicate with each other via a new protocol. SAN is emerging to become the choice of data-storage technology for its significant performance advantages, better scalability, and higher availability over the traditional SCSI buses, and DAS and NAS architecture (Phillips 1998; Farely 2001; Heath 2000; Clark 2003).

This section briefly reviews the early storage technologies, namely, DAS and NAS, and then provides an overview of fibre-channel (FC) SANs with regard to their concept, architecture, and characteristics.

Direct Attached Storage and Network Attached Storage

DAS is a traditional storage technology that uses a dedicated storage server that contains a file system to manage attached storage devices. It frees up the application server

from storage management and allows users to share and back up important data. DAS does have drawbacks: first, it is likely to be a bottleneck if many servers and hosts access the same DAS simultaneously; second, data in a DAS system are accessed indirectly via the storage server; thus, DAS is not optimized for storage management. Figure 1 illustrates the architecture of DAS.

NAS, on the other hand, is a storage system directly connected to LAN and provides file-access services to the computer system. A NAS system usually includes a processor, one or more storage devices containing data, and an interface to LAN. NAS functions like a server that has its own network address. It processes file input/output (I/O) requests via file-access protocols such as the common Internet file system (CIFS) and network file system (NFS). NAS is normally used in enterprises where there is a need to manage a large amount of mission-critical data in a fast, efficient, and robust way. Figure 2 illustrates a typical architecture of NAS.

Figure 2: Illustration of network attached storage

Fibre-Channel Storage Area Network Overview

SAN, defined by the Storage Networking Industry Association (SNIA), is “a network whose primary purpose is the transfer of data between computer systems and storage elements and among storage elements” (Storage Networking Industry Association 2005). Unlike the traditional storage technologies, SAN takes the principle one step further by allowing storage devices to exist on their own separate network and communicate directly with each other at a very high speed. In SAN, clients in LAN access storage devices through servers, whereas servers interact with storage

devices over SAN. Neither of these interactions is required to share the LAN’s bandwidth, as was the case with earlier solutions such as DAS and NAS, thus greatly reducing the network traffic and congestion probability. SAN’s highly flexible and scalable architecture simplifies the management of the ever-increasing storage capacity and reduces various information technology (IT) operating costs such as labor, maintenance, and expansion. Furthermore, the FC infrastructure, which forms the basis of SAN, guarantees faster data-transfer rates (up to 4 Gbps) than that of LAN. This is especially beneficial to e-commerce, for which fast data transactions are important to online companies that are aiming to attract online customers. Figure 3 shows a typical SAN environment.

Fibre channel is a generic name for the integrated set of standards developed by the American National Standard Institute (ANSI) (Technical Committee T11 2006). FC attempts to provide a means for the high-speed data transfer that supports several common transport protocols, including Internet protocol (IP), asynchronous transfer mode (ATM), and small computer system interface (SCSI).

FC first appeared in enterprise networking applications, including redundant array of independent disks (RAID) devices and mass storage subsystems. By the late 1990s, FC was quickly becoming the new connectivity standard for high-speed storage access and server clustering. FC specifications accommodate 133-Mbps, 266-Mbps, 532-Mbps, and 1 Gbps bandwidth (ANSI 2003). However, 4-Gbps FC products are currently available in the market, such as the 4-Gbps host bus adapters (HBAs) of LSI Logic Corporation. FC is unique in its support of multiple interoperable

Figure 3: Illustration of storage area networks

Figure 4: FC five-layer model

topologies, including point-to-point, arbitrated-loop, and switching, and it offers several classes of services (now six classes of services are defined in the new version of the FC standard) for network optimization. Furthermore, with its large frame sizes, FC is ideal for storage, video, graphics, and mass data-transfer applications (Benner 2001; Meggyesi 1994; Kembel 2000).

To clearly illustrate the functionalities of FC, the five-layer concept model is usually used to demonstrate the characteristics of FC, as shown in Figure 4.

This model is composed of five layers from FC-0 to FC-4, as detailed below:

FC-0—The lowest level, specifies the physical features of the media, including the cables, connectors, transmitter and receiver characteristics for a variety of data rates.

FC-1—Defines the transmission protocol, including the 8B/10B encoding/decoding rules used to integrate data with clock information required by serial transmission. In addition, error monitoring, link management, and low-level flow control are done at this layer.

FC-2—Defines the rules for data to be transferred between two ports, the format of FC frame, the mechanisms for controlling the various service classes, and the means of managing the sequence and exchange of a data transfer.

FC-3—Provides common services required for advanced features, such as the ability for more than one port to respond to the same alias address.

FC-4—Provides a set of interface standards to map existing protocols to FC layers.

So far, FC has become the dominant industry standard for SAN, commonly referred to as “fibre-channel SAN” by the SNIA (2005).

The rest of the chapter is organized as follows: in the section on Architectures and Protocols, we will discuss the FC protocol suite and its three typical topologies, in which detailed discussion regarding to characteristics and functionalities of FC layers will be presented. In the section

on Applications, Challenges, and Solutions, we briefly introduce the applications of SAN and the challenges it faces. Subsequently, in the section on Internet SCSI (iSCSI), an emerging technology for SAN, iSCSI, is discussed in detail from its architecture to its security issues. Finally, we will draw conclusions and outline the future of SAN.

ARCHITECTURES AND PROTOCOLS

Fibre channel (FC) was developed as the first successful serial transport with gigabit-per-second rates to provide a practical, inexpensive, yet expandable way for quickly transferring data between workstations, mainframes, supercomputers, desktop computers, storage devices, displays, and other peripherals. Since the end of the past century, FC has been mainly adopted in block I/O applications, especially for SAN. “Fiber” in “fibre channel” refers to the FC’s support for both fiber-optic and copper cabling. “Channel” refers to its role as a gigabit-per-second-rate, high-performance conduit to establish direct or switched point-to-point connection between the communicating devices.

On the other hand, fibre channel is also the generic name of an integrated set of standards developed by ANSI, that will be discussed in detail next.

FC Protocol Suite

The basic fibre-channel standard, fibre-channel physical and signaling interface (FC-PH) (ANSI 1994), defines a point-to-point device interconnection through a switched fabric (Sacks and Varma 1996; Heath 2000). The FC-PH standard also defines the physical layer, transmission, signaling, and framing protocols. The fibre-channel arbitrated loop (FC-AL) standard extends the FC-PH transmission and signaling functions to define a loop interconnection topology that does not require a fabric (ANSI, 1996, *Fibre channel arbitrated loop*).

In April 2003, ANSI approved fibre-channel framing and signaling (FC-FS) (ANSI 2003). Along with fibre-channel physical interface (FC-PI), the FC-FS standard combines FC-PH, its amendments 1 (ANSI 1996, *Fibre*

channel physical and signal interface) and 2 (ANSI 1999), FC-PH-2 (ANSI 1996, *Fibre channel physical and signal protocol-2*), and FC-PH-3 (ANSI 1997) standards. The FC-FS standard deletes outdated functions and features from those standards and includes additional link services in support of new functions defined in the fibre-channel family of documents. FC-FS also includes new improvements and clarifications to the definitions of existing services, which are dictated by the experience of existing implementations. Above the FC-FS and FC-AL protocols layers are FC layer-4 standards, which consist of a set of protocols that map application protocols to the fibre-channel service. Among them, the most widely used application interface is SCSI, which is defined in the fibre-channel protocol for SCSI (FCP) (INCITS T10 2004). The FCP standard describes the protocol for transmitting SCSI commands, data, and status using FC-FS exchange and information units.

Currently, the fibre-channel community has circulated Request for Comment (RFC) documents regarding Internet fibre-channel protocol (Gibbons et al. 2006), fibre-channel management MIB (McCloghrie 2005), and securing block storage protocols over IP (Aboba et al. 2004). Interested readers may refer to the references for more details.

FC Topologies

There are three physical topologies available for FC SAN, namely, point to point, arbitrated loop, and switched fabric. Since the majority of FC SAN configurations in the current market are based on fabric switching, we will focus on the requirements and characteristics of switched fabric while briefly introducing point-to-point and arbitrated-loop topologies.

Point-to-Point Topology

Point-to-point topology is built on a dedicated, point-to-point connection between N_ports of two nodes (Figure 5). An FC port is the entity in the node or fabric of SAN that performs the data communication and transfer. It falls into several categories, including N_port, L_port, and F_port. N_port, known as “node port,” is the node connection

Figure 5: Point-to-point configuration

pertaining to hosts or storage devices in the point-to-point and fabric topology. L_port and F_port, on the other hand, are the entities that are used in the arbitrated loop and fabric loop, respectively.

This topology creates dedicated bandwidth between the pair (normally, between a server and a storage device), with effective throughput of up to 1 Gbps in each direction (ANSI 2003). Before data transactions can be carried out, the two N_ports must perform an N_port log-in to assign N_port addresses or N_port IDs. Thereafter, a persistent connection is maintained, with utilization of the dedicated link determined by the application.

The scalability for the point-to-point topology is rather poor, and there is no resource sharing other than the two connected nodes. Currently, the point-to-point topology is adopted only for a very simple scenario.

Arbitrated Loop

Another way to connect FC nodes is by using an arbitrated loop (FC-AL) (ANSI 1996, *Fibre channel arbitrated loop*). Arbitrated loop allows more than two devices to communicate over a loop ring or hub, as shown in Figure 6.

In the daisy-chain type of an arbitrated loop ring, messages are transmitted from node to node until they reach the appropriate end user, and a fairness algorithm is implemented in FC-AL to ensure that no L_port is blocked from accessing the loop. In this way, a continuous data path exists through all the ports of each node, allowing any node to access any other node on the loop. However, should any link in the loop fail, communication between all L_ports is terminated. The daisy-chain type of FC-AL topology is illustrated in Figure 6a.

(b). Arbitrated loop ring with central hub

Figure 6: Two primary FC-AL topologies

On the other hand, the arbitrated-loop hub helps continuous data communication even when one or more nodes fail. The mechanism lies in the internal architecture of a hub, which connects nodes on a port-by-port basis. The loop hub performs its functionality to sustain the persistent data communication by circumventing the disabled/disconnected node through its bypass circuitry at each port. However, the loop hub is not truly “plug-and-play.” Any time a device is added or removed from the topology, the network must be reinitialized. Figure 6b illustrates the topology of an arbitrated-loop ring with loop hub.

Switched Fabric

The switched-fabric configuration of FC is a routing architecture that delivers the FC frame to the intended receiver based on address information in the header of the FC frame. It provides multiple concurrent connections between any pair of devices using separate paths, thus efficiently reducing the congestion and enhancing the availability. Like a hub, an FC switch connects multiple servers to one FC port on the storage subsystem. With the FC switch, each server shares the bandwidth by rapidly switching from one connection to another, rather than by arbitrating for control of a shared loop. The congestion is hence reduced.

In the pure-loop topology, a host reset or device failure causes a loop initialization that resets all the other devices on the loop; this interrupts the loop’s availability to other servers and storage devices. A switch can prevent this kind of error propagation and can also enable rapid isolation and repair of hardware device failures. Thus, the FC switch enhances availability. Figure 7 shows one possible switch configuration.

The switching mechanism typically used in fabrics is called “cut-through,” which is used to speed packet routing by examining only the link-level destination ID of the FC frame. Based on the destination ID, a routing decision is made by its internal routing logic to switch the FC

Figure 7: Switched-fabric topology

frame to the appropriate port. The destination ID resides in the first 4 bytes of the FC frame header; thus allowing cut-through to be accomplished quickly, without interpretation of anything other than the 4 bytes.

Another superior functionality for the FC switch is its capability to be cascaded to form a complex enterprise SAN, which supports a large number of system hosts and storage subsystems. When switches are connected, each switch’s configuration information is to be copied into all other participating switches. Cascading provides switch topology scalable performance and increased redundancy. Figure 8 illustrates a typical scenario of cascaded FC switches.

All these superior characteristics popularize the switched fabric as the topology choice in the FC SAN industry.

Figure 8: Cascaded FC switches

FC-0: Physical Layer Options

As mentioned above, fibre channel can be run over optical or copper media. At the lowest level, FC-0 defines the physical link in the system, including the fiber, connectors, and optical and electrical parameters for various data rates. At the physical layer, transceivers are devices that have combined transmitters and receivers for dealing with gigabit stream on the circuit boards of HBAs or controller cards. Different types of transceivers are available for both copper and optical media. For copper, transceivers simply perform the function of “electrical in, and electrical out,” whereas for optical media, it performs the function that converts optical pulses into electrical signals, and vice versa. In today’s market, the most widely used transceiver module is the gigabit interface converter (GBIC), which was developed by Compaq, Sun, Amp, and Vixel, and has become the de facto standard in the industry. GBICs are hot-swappable and can therefore be installed and removed while the card/shelf assembly is powered and running. There are two types of GBIC: optical and copper. Optical GBICs are classified into three categories: short-wave laser/multimode, with distance up to 500 m; long-wave laser/single mode, with distance up to 10 km; and extended long-wave laser, with distance up to 80 km. Copper GBICs, on the other hand, are available in two versions: passive (up to 13 m) and active (up to 30 m), and use DB-9 (serial communications D-shell connector, 9 pins) or HSSDC (high-speed serial direct connect) cable interfaces.

FC-1: Data Encoding

In FC, the encoding scheme is defined in the FC-1 layer, which prescribes the serial encoding and decoding rules, special characters, and error control. Owing to the gigabit and multigigabit speed of the FC, an efficient encoding scheme is especially important to achieve DC (direct current) balance and provide enough transitions for clock recovery. Currently, the IBM 8B/10B algorithm is the most widely used encoding scheme for FC. The basic idea of the 8B/10B encoding scheme is to convert every byte of data into one of two possible 10-bit values called “transmission characters.” According to ANSI (1994), each byte of data is denoted in the form of $Dxx.y$ where D indicates the byte being a data byte, xx is the decimal value ranging from 0 to 31, and y is the decimal value ranging from 0 to 7, before it is encoded. For example, Hex $x\text{B7}$, with the binary bit representation of $1011\ 0111$, is divided into the first 3 bits, 101 (decimal 5), followed by the byte’s last 5 bits 10111 (decimal 23). Consequently, the 8B/10B notation refers to $x\text{B7}$ as $D23.5$. This division illustrates the 8B/10B encoding scheme’s internal operation. 8B/10B is realized by processing smaller 3B/4B and 5B/6B modules, followed by their combination to produce the 10-bit transmission character. ANSI (1994) also defines various command characters such as the $K28.5$ command character, to be used exclusively for control purposes.

Since each of the 256 possible 8-bit words can be encoded in two different ways, the 8B/10B encoding scheme is able to achieve long-term DC balance in the data-stream transmission. The 8B/10B encoding scheme also prescribes benefits of simplifying the design of receivers

and transmitters, distinguishing control characters and ordinary data characters, helping clock synchronization, and improving error detection.

FC-2 Layer

The signaling protocol (FC-2) level serves as the transport mechanism for the fibre channel. The framing rules of the data to be transferred between ports, the different mechanisms for controlling the six service classes (see the section on Class of Service below), and the means of managing the sequence of a data transfer are defined by FC-2 (ANSI 2003; Clark 2003). In this section, we will mainly focus on the following five aspects of FC-2:

- Ordered sets
- Framing protocol
- Sequence and exchange
- Flow control
- Class of service

Ordered Sets

The ordered sets, with 40-bit-long command syntax, contain data and special characters that have a special meaning. Ordered sets are used to facilitate bit and word synchronization, as well as to establish word boundary alignment. The ordered sets fall into three general categories: frame delimiters, primitive signals, and primitive sequences.

The frame delimiters include start of frame (SOF) and end of frame (EOF) ordered sets. The SOF delimiter is used in a frame header to initiate a connectionless level of service. Following the SOF ordered set, up to 2112 bytes of data would compose the body of the frame. An EOF ordered set is used to indicate that the frame transmission is complete. Fibre channel defines eleven types of SOF ordered sets, and eight types of EOF ordered sets (ANSI 2003).

Primitive signals are ordered sets designated by the standard to indicate actions or events on the transport. There are two ordered sets: idle primitive and receiver ready (R_RDY) primitive. An idle primitive is a primitive signal used as a fill word between two data frames during the inactivity period. The R_RDY primitive, on the other hand, is used to indicate that the interface buffer is available for receiving further frames.

Primitive sequences are a group of ordered sets used to indicate or initiate state change on the port. Unlike primitive signals, primitive sequences require consecutive detection of three words before any action is taken. When a primitive sequence is received and recognized, a corresponding primitive sequence or idle needs to be transmitted in response. The primitive sequences supported by the FC standard are offline (OLS), not operational (NOS), link reset (LR), and link reset response (LRR).

Framing Protocol

The data must be framed as separated data packets to be transported in FC. The data packets are referred to as “FC frames.” There are two types of frames in fibre channel: data frames and link-control frames. The two types

Figure 9: FC frame format

of frames have the same header format. The difference between the two frames is that link-control frames have no data payload, whereas the data frames can have as many as 2112 bytes of data after the header. Figure 9 illustrates the format of a FC frame.

As shown in Figure 9, frames are always started with an ordered set SOF. This is an encoded 4-byte word that defines the class of service and specifies whether or not the frame is the first in a series of related frames. Following the SOF, an encoded 24-byte frame header is used for link control and for detecting missing or out-of-order FC frames. Frame header contains eleven types of information, including destination identifier (D_ID), source identifier (S_ID), class specific control (CS_CTL), sequence identifier (SEQ_ID), and sequence count (SEQ_CNT) (ANSI 2003).

After the header, the data field varies from 0 to 2112 bytes. The variable length of the data fields facilitates FC's various applications to achieve an optimal trade-off between the frame overhead and the data payload. Following the data field, cyclic redundancy check (CRC) is used to check the data integrity within the frame. An EOF ordered set is finally appended to notify the recipients of the completion of the frame.

After the frame is assembled, the frames are delivered via a protocol hierarchy of the sequence and exchange, as discussed below.

Sequence and Exchange

A sequence is formed by a set of FC frames with a common sequence ID (SEQ_ID), corresponding to one message element, I/O block, or information unit. Sequences are transmitted from an initiator (usually an N_port) to a recipient, with an acknowledgment, if applicable. Error recovery is usually performed at the sequence level for efficiency. For example, if an FC frame fails the CRC check, it is more efficient to recover the entire sequence at gigabit speed than to embed the logic required to track and recover individual frames.

An exchange, on the other hand, is composed of one or more nonconcurrent sequences passing between two FC ports. An exchange usually corresponds to a single operation such as a SCSI task or an IP exchange and may be unidirectional or bidirectional. Sequences in an exchange have a common originator exchange identifier (OX_ID) and a responder exchange identifier (RX_ID), and only one sequence can be active at any one time. However, sequences of different exchanges may be concurrently active.

At the FC-2 layer, two nodes in the FC SAN system communicate with each other by establishing one or more exchanges simultaneously, with unique exchange IDs and sequence IDs registered in each FC frame. This nested

structure maximizes the utilization of the link between two nodes, with minimal overhead for setting up and tearing down logical connections.

Flow Control

It takes finite time for a receiver to process incoming frames. If the second frame arrives while the receiver is still processing the first frame, it must be queued up in buffers. Since the amount of buffers is finite in each port of a receiver, the receiver must be able to regulate the rate at which frames are sent from the sender; otherwise, the port will be overwhelmed with frames. Thus, FC provides two flow-control mechanisms, buffer-to-buffer flow control and end-to-end flow control, based on a system of credits.

The concept of credits refers to the "permission" granted by a receiving port to a sending port to send a specified number of frames, and the number of frames that may be sent is referred to as the "available credit" of the receiving port. As long as a port has a nonzero available credit, it has permission to send a number of frames up to that of the available credit. When a frame is sent, the available credit is decremented by one. When a response is received, the available credit is incremented by one. If the available credit reaches zero, frame transmission is suspended until the available credit is refreshed to a nonzero value.

Just as there are two types of flow control, there are two types of credits: buffer-to-buffer (BB_Credit) and end-to-end credit (EE_Credit). Credit is granted during the log-in process and is based on the resources available in the receiving port.

Buffer-to-Buffer Flow Control. Buffer-to-buffer flow control, referred to as BB_Credit, is used by class 2 and class 3 services to ensure that the next node in the path has resources available to which it is attached. When one of the applicable frames is sent, the available BB_Credit is decremented by one, until the BB_Credit is exhausted to zero. The receiver will respond with the "receive ready" primitive R_RDY to the sender for every received FC frame. Accordingly, BB_Credit in the sender is incremented by one for each received R_RDY. However, the BB_Credit in no way guarantees that the final destination has the resources to process the frame; this task is fulfilled by end-to-end flow control. Figure 10 illustrates the scenario of buffer-to-buffer control for a pair of nearby nodes A and B with four available BB_credits.

End-to-End Flow Control. "End-to-end flow control" refers to the flow control between a source-node port and a destination-node port. Much like buffer-to-buffer flow

Figure 10: BB_Credit control with four available BB credits. Nodes A and B are a pair of nodes next to each other with buffer-to-buffer flow control. After the log-in process, four available BB credits are allocated to node A, which permits A to send up to four data frames (frames 1, 2, 3, and 4 in the figure). Node A decrements its BB_Credit by one for each frame sent, and is suspended for transmission after all four BB credits are exhausted (i.e., the available credit = 0). Thereafter, node A becomes idle until its BB_Credit is replenished by receiving R_RDY from node B.

control, during the log-in process, the destination node grants end-to-end credits (EE_Credit) to the source node. The EE_Credit is thereafter maintained by the source node for future communication. Unlike BB_Credit, the “Ready” signal in controlling EE_Credit is ACK, an FC frame with a full header and no data payload, rather than the R_RDY primitive. The source node decrements EE_Credit by one for each FC frame sent and increments EE_Credit by one for each ACK received. EE_Credit is used by class 1 and class 2 services. Figure 11 illustrates the EE_Credit control between a pair of source/destination nodes with four available credits.

Class of Service

A significant problem in designing a data communication system is to ensure proper data transmission that requires different levels of delivery guarantees, bandwidth, and connectivity between communicators. The concept of class of service is therefore proposed as an indication of what kind of service communicators request from the network. To address this issue, the FC protocol specifies six classes of service, namely, Class i , with $i = 1, 2, \dots, 6$. Different classes of services determine different types of flow control and resource for regulating transmission:

Class 1 service—defines a dedicated connection between two devices with frame delivery acknowledgment.

Because of the nature of the dedicated connection, there is no need for buffer-to-buffer flow control; the fabric does not need to buffer the frames as they are routed. Thus, only end-to-end flow control is used in class 1 and a heavy burden is placed on the FC switches. Furthermore, since class 1 is dedicated, established class 1 connections cannot be shared even when the connections are idle (i.e., no traffic). Thus, multiple connections of class 1 service would quickly consume the resource, and prevent the switch from serving other requests.

Class 2 service—is a connectionless class of service with confirmation of delivery, or notification of nondeliverability of frames, and no bandwidth is allocated or guaranteed. In the switched-fabric environment, it is the responsibility of the fabric to provide appropriate congestion control to prevent bandwidth hogging and starvation of ports. Class 2 is suitable for mission-critical applications that need verification via frame acknowledgments to guarantee data integrity.

Class 3 service—is a connectionless class of service providing a datagram-like delivery service with no confirmation of delivery and no notification when the frame is undeliverable. If a frame cannot be delivered or processed, it is discarded without notification. When such errors happen, class 3 relies on the upper level to recover the error. As compared with classes 1 and 2,

Figure 11: EE_Credit control with four available EE credits. Nodes A and B are a pair of source/destination nodes with end-to-end flow control. After the log-in process, four available EE credits are allocated to node A, which permits A to send up to four data frames (frames 1, 2, 3, and 4 in the figure). Node A decrements its EE_Credit by one for each frame sent, and is suspended for transmission after all four EE credits are exhausted (i.e., the available credit = 0). Thereafter, node A becomes idle until its EE_Credit is replenished by receiving ACK from node B.

class 3 provides the fastest transmission by sacrificing a certain degree of reliability. Class 3 service is best suited for time-critical applications such as real-time broadcasting.

Class 4 service—introduces the concept of virtual circuits for the FC architecture. Like class 1, class 4 service is connection-oriented. The difference is that, unlike class 1 service, which allocates the entire bandwidth to a communication pair, class 4 service provides fractional bandwidth as well as different quality of service (QoS) allocations. In addition, the multiple virtual circuits facilitate time-sensitive applications such as real-time videos. However, this functionality of class 4 service also poses challenges to the FC switch design, as the switch must maintain and monitor potentially hundreds of virtual circuits with variable QoS. The basic idea for Class 5 service is to provide isochronous, just-in-time service. However, it is still undefined, and possibly may be scrapped altogether. It is not mentioned in any of the FC-PH documents.

Class 6 service—provides support for multicast service with acknowledged delivery through a fabric. In the multicast scenario, if numerous target devices in the multicast group respond to the initiator with acknowledgments, thus flooding the initiator, the topology might be overwhelmed. Class 6 service alleviates this problem by placing a multicast server into the

configuration. Class 6 service is also known as unidirectional dedicated connection service.

Although class 4 and class 6 services are described in detail in FC documents, they are actually not widely adopted in FC products. Class 2 and class 3 services, on the other hand, are the most widely used services because of their simplicity and efficiency. FC switches, for example, typically support only class 2 and class 3 services, an indication of the predominant market trend of the technology.

FC-3: Common Services

The FC-3 layer of the FC standard is still under deliberation and intended to provide the common services for advanced features, including striping, multicast data encryption, and data compression. For example, striping is used to increase the transmission rate of the data stream by transmitting data out of all N_{ports} simultaneously.

FC-4: Interface Layer

FC-4 establishes the interface between fibre-channel and upper-level applications, and specifies the mapping rules for upper-layer protocols to use the FC levels below. Fibre channel's FC-4 level has been documented in several standards describing how different upper-level protocols can make good use of the transport services provided by

FC-2, FC-1, and FC-0. These standards define the mapping of the following interface and protocols to FC:

- small computer system interface (SCSI)
- intelligent peripheral interface (IPI)
- high-performance parallel interface (HIPPI) framing protocol
- Internet protocol (IP)
- IEEE 802.2

Among these, the SCSI fibre-channel protocol (FCP) is most widely used (INCITS T10 2004; Wang et al. 2003). We will take SCSI FCP as an example to illustrate how the mapping scheme works.

The FCP initiator is responsible for mapping I/O traffic into FCP information units (IUs), and processes various IUs. The FCP-2 standard defines four FCP IUs: FCP_CMND, FCP_DATA, FCP_XFER_RDY, and FCP_RSP. All, except FCP_DATA, have well-defined packet formats.

When the SCSI request arrives at the FCP initiator, the FCP initiator fetches each coming request and encapsulates it into FCP_CMND. The FCP_CMND is then sent through the HBA and FC port. After having received FCP_CMND, the FCP target de-encapsulates FCP_CMND and processes the SCSI command.

In the case of the FCP read operation, the FCP target de-encapsulates the received FC frame into the SCSI request, and prepares for the requested data. When the data are ready, the FCP target will continuously transmit the requested data back to the FCP initiator until all the data are transferred. The FCP target will then immediately issue the completion message FCP_RSP to the initiator. With a FCP write operation, the FCP target will send out FCP_XFER_RDY to the FCP initiator after allocating sufficient space for coming data. When FCP initiator receives FCP_XFER_RDY, it will begin to transmit the write data until completion. Finally, when the target receives all the data successfully, it will send back FCP_RSP to the initiator indicating the completion of the FCP operation (Figure 12).

APPLICATIONS, CHALLENGES, AND SOLUTIONS

In this section, we will introduce some typical applications for FC SAN such as data consolidation and disaster recovery as well as challenges faced by FC SAN; some recently proposed solutions to meet the challenges are discussed in more detail.

Fibre-Channel Storage Area Network Applications

Although storage networks share common components in the form of servers, storage, and interconnection devices, the configuration of a SAN is determined by the upper-layer applications it supports. Currently, FC SAN is widely used in various applications such as storage consolidation, disaster recovery, server clustering, and remote data replication. In this section, we will take storage consolidation and disaster recovery as examples for illustration.

Figure 12: FCP operation

Storage Consolidation

Storage consolidation is performed by SAN to combine and consolidate the direct storage resources by each server, so that the maintenance cost is reduced and storage investment is more efficiently used. Traditionally, when an individual file or application server exhausts its storage resources, the IT administrator is forced to purchase a new storage device for more storage space. Over time, a data center is accumulated, with hundreds of servers, each with its own direct attached storage. This does not scale well, because a much larger IT staff is needed to maintain the servers for backups and updates. Moreover, since each server's utilization is not balanced, some may have a large percentage of free space while others may exceed their capacities; SANs offer a powerful solution for consolidating storage resources to improve the efficiency of the business environment, by breaking the direct connection between servers and storage, and combines both on a common network. SANs link multiple storage systems and servers over a high-speed network and allow the sharing of expensive tape devices and disk arrays. In this way, the storage devices can be constructed as separate, shared, and manageable resources (Figure 13).

Disaster recovery

Disaster recovery is the process of restoring operations of a business or organization in the event of a catastrophe. It is another important application of SAN. Traditionally, disaster recovery requires daily offsite backups. In a worst-case scenario, the offsite would be lagging by between 24 and 48 hours. In today's competitive economy, losing a day's worth of transactions may cause bankruptcy. The time between the last-stage backup and the point of failure is called the "recovery point." In contrast, recovery time includes the time elapsed from the time when the disaster occurs to the resumption of normal business

Figure 13: SAN solution for storage consolidation

activities. Currently, many organizations and companies have placed disaster recovery at a high priority, with IT administrators scrambling to implement disaster-recovery strategies within the confines of budget and personnel limitations.

Challenges

After 9/11, disaster recovery is becoming a critical part of IT spending for many companies. It was observed that even though a server machine may be very robust and highly fault-tolerant, it was still vulnerable to an unexpected catastrophe such as a natural disaster or a planned attack. All of the stored data and computing equipment could be wiped out instantly. Many companies have thus deployed FC SAN for data disaster recovery. Some of the applications currently supported by FC SAN, such as storage consolidation, data replication, backup, and recovery, have also been deployed.

FC SANs were, however, originally designed to operate within a limited distance such as a campus. This is not sufficient to safeguard corporate data. Owing to widespread power outages, caused by natural calamities such as earthquakes and by terrorist attacks, the distance expansion needed for robust disaster recovery planning has skyrocketed. The primary and secondary sites have to be physically separated by up to hundreds or thousands of miles, so that only one site will be affected in the event of a disaster.

The power-grid failure that occurred in Northeastern United States in August 2003 once again illustrates that a data disaster-recovery system within a small distance is not in keeping with business continuity. In this incident, the total business loss was estimated to be 2 billion dollars; the loss is in million dollars per hour during the 2 days' down time. From this incident, for more reliable

data storage, companies need data recovery over long distances. Extending FC SAN over long distances (up to hundreds or thousands of miles) thus becomes the research focus of network storage.

The distance constraint of FC SAN is attributed to many factors, such as the flow-control protocol and application sensitivity to the round-trip time. New solutions are urgently sought to extend SAN islands into longer distances.

New Solutions

As mentioned in the previous section, an essential step in disaster recovery is to create a secondary site with the same capacity and performance as the primary site, and to make sure that primary and secondary SAN sites are geographically dispersed by long distances (up to hundreds or thousands of miles), so that only one site will be affected in the event of a disaster. SAN extension is hence becoming a significant technology for enterprise business continuity. An extended SAN increases the geographic distance allowed for SAN storage operation, in particular, for data replication and backup.

Consider further the requirements of FC SAN extension. For long-distance data replication and remote backup, there are a wide range of technologies involved, such as synchronous, asynchronous, and semisynchronous replication (Telikepalli et al. 2004). Of these technologies, synchronous data replication has a limitation on the distance between SAN islands because of its low tolerance to delays. Since synchronous replication implies real-time replication, the initiator must wait for an acknowledgment from the target in the remote site before the write operation is complete. This will cause longer round-trip times and slow down the available speed of writing data to the local devices. In asynchronous replication, the local write

can be completed before receiving the acknowledgment from the remote site, thus making more efficient use of the available bandwidth. However, asynchronous replication also needs to be completed within a specified window, in order to avoid queuing that results in long data transfer latencies or frame loss. A huge amount of data has to be replicated within a few hours. Thus, SAN extensions must have adequate transfer capability to transport such an amount of data within the given time limit. Therefore, high throughput and low latency become the key requirements for the SAN extension solution.

Some new solutions have been proposed for FC SAN extension, such as extending FC SAN over IP-based technology, FC SAN over synchronous optical network (SONET), and FC SAN over wavelength-division multiplexing (WDM).

FC SAN Extension over IP-Based Technologies

IP-based extension solutions (Clark 2002) are emerging technologies that encapsulate SCSI and FC frames into standard IP frames to be transported over IP networks. Several protocols, including Internet SCSI (iSCSI), fibre channel over TCP/IP (FCIP), and Internet fibre-channel protocol (iFCP) have been introduced to transport the SCSI commands and responses, either by major vendors or the IP Storage Working Group of the Internet Engineering Task Force (IETF).

Internet SCSI (iSCSI). iSCSI is based on the SCSI protocol, which enables the host computer systems to perform data I/O operations with a variety of peripheral devices. iSCSI uses the TCP/IP suite for the transport of SCSI commands, and depends on a client/server architecture, with the clients being the SCSI initiators and the server being the SCSI target. The central mission of iSCSI is to encapsulate and reliably deliver data-block transactions between initiators and targets over TCP/IP networks.

iSCSI is currently being standardized by IETF (Bakke et al. 2005), in which iSCSI sessions, session management, and other aspects of iSCSI are being defined.

iSCSI is receiving more attention in recent years because it changes the price point of SAN so dramatically. It is hard to overstate how much different the world of SANs will become as iSCSI SANs become more popular. As such, in the next section, on Internet SCSI, we will have a more detailed discussion of iSCSI regarding its architecture, protocol-layer model, session management, and other relative issues.

Fibre Channel over TCP/IP. FCIP is a TCP/IP-based tunneling protocol for connecting geographically distributed FC SANs transparently to both FC and IP. FCIP gateways are located at the interface of the FC fabric and IP network, and are responsible for encapsulating and de-encapsulating FC frames. Essentially, the goal of FCIP is to interconnect geographically dispersed SANs through reliable high-speed links.

The first step of implementing FCIP is to encapsulate FC frames into IP packets and map FC fabric domains to IP addresses. Two sessions will be set up. One is an end-to-end session between FC devices that are based on the FC protocol. The other is the TCP/IP session between the gateways in the IP network. Unlike other IP-based technologies, which use native IP connections between individual storage devices, FCIP provides IP connections between FC SAN only at the FCIP tunneling devices at each end point of the IP network. The existence of the FCIP device and the IP network is transparent to the FC switches, whereas the FC connection buried in the IP datagram is transparent to the IP network. The FCIP protocol is compatible with ANSI FC standards and is being defined in an IETF draft (Natarajan and Rijhsinghani 2005). FCIP is illustrated in Figure 14.

Internet Fibre-Channel Protocol. iFCP is a gateway-to-gateway protocol to transport FC frames over TCP/IP switching and routing elements. According to the IETF draft (Gibbons et al. 2005), the protocol enables attachment of existing FC storage products to an IP network.

Figure 14: FCIP scenario

Figure 15: iFCP scenario

Figure 16: SAN extension over SONET

An iFCP fabric supports only classes 2 and 3 FC transport services.

iFCP assigns an IP address to each storage device in SAN. This allows communication between host and storage devices through standard IP switches and routers. In addition, iFCP provides flexible routing throughout the network, and servers from any locale can access storage resources on another. This facilitates remote mirroring and data-replication applications, as well as centralized backup and disaster recovery. The difference between FCIP and iFCP is that FC commands and data terminate in iFCP gateways, hence making the design of the iFCP gateway critical for achieving high application throughputs (Figure 15).

FC SAN Extension over Synchronous Optical Network

Synchronous optical network (SONET) is the transmission and multiplexing standard for high-speed traffic. SONET is mainly used in metro or backbone transport networks for transporting IP and ATM traffic.

The basic idea of extending FC SAN over SONET is to map FC frames onto SONET tributaries for transport across metro/regional add-drop (ring) and switching gateways. Other schemes have also added an intermediate ATM

layer, so that FC frames will first be mapped into ATM cells before mapping onto SONET tributaries for transmission. In SONET, data are passed through dedicated channels at rates from 155 Mbps up to 4 Gbps. Data paths are not changed rapidly, as they are with routed IP networks. Instead, they are provisioned and remain rather static. Each dedicated channel is given a guaranteed fixed bandwidth for the data. SONET infrastructure is widely deployed, on top of which ATM and IP ride to provide voice and data transport, thus eliminating unnecessary overheads. Other advantages of the SONET-based extension solution include good availability and fast rebooting capability (Sorrento 2003; Helland 2002). Figure 16 illustrates the typical scenario of extending SAN over SONET.

FC SAN Extension over Wavelength-Division Multiplexing

Wavelength-division multiplexing (WDM) has emerged as a promising solution for the FC SAN extension. Compared with the existing technologies, extending FC SAN over WDM has the advantage of unsurpassed scalability, multiprotocol transparency, topological flexibility, and survivability (Murthy and Gurusamy 2001; Cisco Systems 2001; Telikepalli et al. 2004).

Figure 17: SAN extension over DWDM (GE = gigabit Ethernet; OEO = optical-electrical-optical; OADM = optical add/drop multiplexer)

WDM transmits multiple FC frame exchanges on a single fiber using different wavelengths. WDM is transparent because it will not change the original ways of transmission. Essentially, WDM provides virtual channels for FC transmission with path protection. WDM divides bandwidth on a fiber into several nonoverlapping channels (wavelengths) and realizes simultaneous message transmissions on different wavelengths on the same fiber. There are two types of WDM technologies: dense wavelength-division multiplexing (DWDM) and coarse wavelength-division multiplexing (CWDM).

FC extension over WDM can be used for either switch-to-switch or switch-to-node connectivity. As long as the link is stable, the connection presents no major difficulties. If the link fails, however, each node would undergo fabric reconfiguration, with all storage conversations suspended until each fabric is stabilized. Figure 17 illustrates FC SAN extension over a DWDM scenario.

INTERNET SCSI (iSCSI): AN EMERGING TECHNOLOGY FOR SAN

When we look at the various techniques for IP-based SANs, it is interesting to notice that FCIP is an extreme

case of IP-based SANs, in the sense that it adopts many concepts of FC SAN and some from TCP/IP. In this sense, FCIP can be regarded as a simple extension of FC SAN, rather than a real migration from FC to IP-based storage. On the other hand, iSCSI protocol is another extreme case in the sense that it totally eliminates the FC concepts by replacing both FC fabrics and FC device interface with a native IP protocol. The development of iSCSI fulfills the market demand to leverage the available Ethernet and IP infrastructures, and has hence received much attention from all major storage and storage solutions providers (SNIA 2004; Zamer 2004; Clark 2003).

iSCSI Network Architecture

As illustrated by Figure 18, the goal of iSCSI is to establish SAN by using an initiator/target mechanism through IP networks. When an application or user issues a request for data, a file, or an application, the operating system generates the SCSI commands or data request. The command and request are then encapsulated, and a packet header is added. The packets are transmitted over an Ethernet connection. At the receiving end, the packet is disassembled, separating the SCSI commands and data. Finally, the SCSI commands and data are sent to the SCSI storage device.

Figure 18: iSCSI scenario

One of the fundamental problems that iSCSI has to solve is the storage-relative network intelligence (Clark 2003). Unlike the FC SAN environment, in which FC devices provide network intelligence such as log in, device discovery, and state-change notification, iSCSI leverages on current Ethernet and IP infrastructures, which do not possess storage-specific intelligence. Therefore, an iSCSI device itself must install such intelligence to deal with all the storage relative requirements.

iSCSI Protocol-Layer Model

iSCSI uses TCP/IP for reliable data transmission over potentially unreliable networks. Figure 19 shows the iSCSI protocol-layer model, which provides an idea of an encapsulation order of SCSI commands for their delivery through a physical carrier. As illustrated by Figure 19, an initiator (server or workstation) initiates requests for data reading or writing from a target (a data-storage system). These requests are sent through a SCSI commands set, command descriptor block (CDB), in SCSI layer (INCITS 2004). The iSCSI layer then provides interfaces to the standard SCSI commands set and encapsulated CDB with data and status-reporting capacity. Encapsulation and reliable delivery of CDB transactions between initiators and targets through the TCP/IP network is the main function of the iSCSI, which is to be implemented in the potentially unreliable medium of IP networks.

The iSCSI protocol monitors the block data transfer and validates completion of the I/O operation. The data transfer is carried over one or more TCP connections between the initiator and target. Even though a single TCP connection is sufficient to establish communication between an initiator and a target, it is often advantageous to use multiple TCP connections (Meth and Satran 2003) for the following reasons:

- A single TCP connection is often not possible to achieve the maximum bandwidth of the underlying physical interconnect.

- A multiprocessor machine that allows separate threads running on the different processors may require simultaneous utilization of different TCP connections.
- When there are multiple target resources through different physical interconnects, their bandwidth can be aggregated by spreading multiple TCP connections over all the possible physical interconnects.

iSCSI Address and Naming Conventions

Because the iSCSI devices are participants in an IP network, they have individual network entities to identify their assigned network addresses. Each network entity can have one or several iSCSI nodes (Figure 20).

An iSCSI device is identified by a unique global iSCSI name. An iSCSI name is a 255-byte-long, human-readable identity for a storage device that is used to discover an I/O process and validate a device via the iSCSI log-in. An iSCSI name is usually composed of three parts: a type designator, a naming authority, and a unique identifier assigned by the naming authority. For example, “fqn.com.njit.storage.itdepartment.100” is a typical iSCSI name with “fqn” the designator, “(reversed) njit.com” the naming authority, and “storage.itdepartment.100” the unique identifier assigned by the naming authority. The iSCSI name is processed by the domain name system (DNS).

The iSCSI name, however, is not used for routing because its 255-byte length will greatly increase routers’ burden. Instead, the iSCSI network portal is used to perform such a function. The iSCSI network portal is the combination of an iSCSI node’s assigned IP address and TCP port number. Once the IP address and TCP port number are established for a specific iSCSI node, only the IP address/TCP port combination is required for handling data transfer.

The separation of the iSCSI name from the iSCSI network portal provides a correct identification of an iSCSI device irrespective of its physical location. Even if a storage device is moved and given a different IP address and

Figure 19: iSCSI protocol model

Figure 20: iSCSI name entities

TCP port number, its iSCSI name is always kept unaltered, thus allowing itself to be rediscovered. Moreover, the iSCSI network protocol together with iSCSI names provide a support for aliases that are reflected in the administration systems for better identification and management by system administrators.

Session Management

An iSCSI session is a collection of TCP connections between an iSCSI initiator and an iSCSI target used to pass SCSI commands and data. It consists of a log-in phase and a full-feature phase, which is completed with a special command.

In the log-in phase, the log-in negotiation is performed to exchange parameters and a corresponding range of values. After successful log-in (if not, the log-in is rejected and TCP connections are closed), the initiator will generate initiator session ID (ISID), which will be used together with its iSCSI name to uniquely identify this particular session. Likewise, the target will generate target session ID

(TSID), together with its iSCSI name, to uniquely identify the session. Thereafter, one or multiple TCP connections will be set up for this ISID/TSID pair, which is illustrated in Figure 21.

Once the log-in phase is complete, the iSCSI session turns to the full-feature phase. If multiple TCP connections have been set up for that session, individual command/response pairs must flow over the same TCP connection, which is known as “connection allegiance.” Connection allegiance policy is adopted to avoid extra overhead to monitor multiple TCP connections and to enhance the bandwidth utilization. An iSCSI read command, for example, is transmitted through a single TCP connection, until the completion of this transaction. Note that iSCSI connection allegiance is per command, not per task.

Error Handling

Unlike the SCSI protocol, which assumes an error-free environment because of its utilization of a dedicated parallel bus, the iSCSI protocol provides a great number

Figure 21: iSCSI session management

of measures for handling errors, owing to a high probability of errors in data delivery in some IP networks, especially WAN.

As such, iSCSI requires both the initiator and the target to have the ability to buffer commands and respond with acknowledgments. In case of protocol data units (PDUs) that are in error or are missing, the iSCSI end device must be able to retransmit the missing or corrupted PDUs.

iSCSI provisions a three-tier hierarchy of error handling and recovery. At the SCSI level, errors are recovered within a SCSI task, by repeating transfer of lost or damaged PDUs. Such errors occur infrequently because of the use of a parallel bus at the SCSI level. At the TCP level, a TCP connection may fail, in which case the TCP connection is recovered by a command restart. If multiple TCP connections are used for an iSCSI session, the reconstruction of each individual connection is required. Finally, the iSCSI session itself can be damaged. Termination and recovery of a session are usually not required unless both other levels fail to recover. Such a situation requires that all TCP connections be closed, all tasks terminated, and the session restarted via a repeated log-in.

Security

Because iSCSI data will go through WAN, the potentially insecure public IP network, data integrity and security become key issues. TCP itself can provide a basic level of end-to-end data integrity through the standard checksum. However, iSCSI will have to provide more data integrity and security options if stricter security requirements are needed.

IP security (IPSec) is transparent to higher levels, including iSCSI. Hence, iSCSI can leverage on IPSec to perform authentication between the initiator and target, authentication and data integrity, and finally, data encryption. Various solutions can be used for authentication, such as Kerberos or private keys exchange (Clark 2003).

CONCLUSION

In this chapter, we have provided an overview of the evolution from DAS and NAS to SAN. We have described the fundamentals of SAN—i.e., fibre channel protocol and its five-layer model. Moreover, we have presented the iSCSI protocol as the emerging technology for the next-generation SAN.

We first focused on the fibre channel by analyzing its protocol suite, topologies, and the five-layer model. We introduced the integrated set of FC standards defined by ANSI, and presented three types of FC topologies: point to point, arbitrated loop, and switched fabric. Thorough understanding of the five-layer model of the FC is essential for the study and design of SANs. We thus reviewed various aspects of the five-layer model, ranging from the physical-layer options of FC-0 to the mapping interface of FC-4. We then presented two typical applications of FC SAN, namely, data consolidation and disaster recovery, and introduced several proposed

solutions for FC SAN extensions to mitigate the distance constraint.

As the newly emerging protocol for SAN, iSCSI has drawn much attention from all major storage vendors and storage solution providers. We thus provided a detailed discussion of various aspects of iSCSI, from the iSCSI network architecture to iSCSI security.

The future of SANs is being shaped by a spectrum of existing and emergent technologies, and the real-world applications they are designed to serve. We believe that two trends for SANs are emerging: first, the IP-based SAN technologies, especially iSCSI will play an increasingly important role in network storage; secondly, SAN will eventually be integrated with the mainstream core networking, as the core value of SANs is based on affordable and supportable by mainstream technologies.

GLOSSARY

ANSI: American National Standards Institute.

CIFS: Common Internet file system. CIFS is a network file system access protocol primarily used by Windows clients to communicate file access requests to Windows servers.

CRC: Cyclic redundancy check. CRC is used to check the correctness of transmitted data

DAS: Direct attached storage.

EOF: End of frame. EOF is used in the header of an FC frame to indicate the end of a FC frame.

Exchange: A set of non-concurrent sequences for a single I/O operation.

FC: Fibre Channel. FC is a collection of standards for high-speed data transmission. It supports point-to-point, arbitrated, and fabric topologies.

FCIP: Fibre channel over TCP/IP. FCIP is a TCP/IP-based tunneling protocol for connecting geographically distributed FC SANs transparently over IP.

F_port: The “fabric” port within an FC fabric switch.

GBIC: Gigabit interface converter. GBIC is the widely used transceiver to convert electrical signal in host bus adapters (HBAs) into optical or electrical signals for transmission.

iFCP: Internet fibre-channel protocol (iFCP). iFCP is a gateway-to-gateway protocol to transport FC frames over TCP/IP switching and routing elements.

iSCSI: Internet SCSI. iSCSI is based on the small computer systems interface (SCSI) protocol, which enables the host computer systems to perform data I/O operations with a variety of peripheral devices.

L_port: The “loop” port performing an arbitrated-loop function.

NAS: Network attached storage.

NFS: Network file system. NFS is a distributed file system originally developed by Sun Microsystems Computer Corporation.

N_port: Node connection associated with hosts or storage devices in the point-to-point and fabric topologies.

RAID: Redundant array of independent disks. RAID is a family of techniques for managing multiple disks to deliver desirable cost, data availability, and performance characteristics to host environments.

SAN: Storage area network.

Sequence: A set of related frames transmitted unidirectionally from one N_Port to another.

SNIA: Storage Networking Industry Association.

SOF: Start of frame. SOF is used in the header of a FC frame to indicate the start of a FC frame.

SONET: Synchronous optical network. SONET is a widely used transmission and multiplexing standard for high-speed traffic in North America.

WDM: Wavelength-division multiplexing.

INTRODUCTION

The public switched telephone network (PSTN) was originally modeled along two major principles: (1) the offering of a single-service voice communication, between two parties, and (2) the fact that this service would be offered by means of a complex network equipped with rather simple terminal devices. This model worked well until the 1960s, when major network companies realized that advances in information technology (IT) could create additional revenue streams via the provision of services other than voice communication. Initially, the deployment of these extended services, such as call waiting, took place using stored program control (SPC) switching systems. SPC was a monolithic architecture that required programming of services in the switch.

In the mid 1970s, the common channel signaling network (CCSN)—more widely known as signaling system no. 7 (SS7)—was introduced. The CCSN architecture realized out-of-band signaling by providing separate network links for signaling and voice information. Also SS7 provided for a standardized switching protocol suite effectively liberating telecom operators from their dependence on specific switching equipment manufacturers. The IN concept was born out of SS7 in the early 1980s and became a very cost-effective solution for service provision in telephony because it allowed for extended services with minimum modifications in the network architecture.

From then on IN has successfully adapted to every major leap in either network or service provisioning technology. The following paragraphs detail the evolution from the original IN concept to the elaborate distributed intelligent broadband network (DIBN). Initially, the traditional IN model is presented in order to familiarize the reader with the relevant terminology as well as basic concepts. Consequently, the transition towards the intelligent broadband

network (IBN) architecture is briefly presented, followed by an analysis of the incorporation of distributed processing and mobile code technologies, common object request broker architecture (CORBA) and mobile agents, to IBN resulting in the DIBN. Moreover, various approaches for open service provision via DIBN are analyzed, focusing on the adoption of the parlay APIs. As a final step, we discuss the gradual replacement of the IN concept in the context of the upcoming next generation networks (NGN).

INTELLIGENT NETWORK BASICS

The major innovation of IN was that it enabled operators to move the main bulk of service execution out of the switching elements and into a dedicated service-execution node. This way an operator could have a central point for managing and deploying services that was decoupled, to a certain extent, from the switching infrastructure.

Of course, for realizing the full potential of such a concept, certain international network standards had to be devised. An effort toward standardization was undertaken by the International Telecommunications Union (ITU) and the European Telecommunications Standards Institute (ETSI) and led to Intelligent Network Conceptual Model (INCM), which is described in the Q120x series of standards from the ITU. A similar effort was carried out in North America, resulting in the Advanced Intelligent Network (AIN) series of standards.

INCM prescribes four planes, which relate to IN implementations as shown in Figure 1. The INCM adopts a service-oriented approach; thus, the top plane is the service plane (ITU-T [Telecommunication Standardization Sector of the International Telecommunication Union] 1997 Q.1202). The service plane provides a view of the available IN services but with no implementation details.

Figure 1: INCM and IN implementation (CCF = call control function; IP = Internet protocol; SCF = service control function; SCP = service control point; SSF = service switching function; SSP = service switching point)

Services are composed by service features (SFs), which are the smallest functions on this plane. The service plane is also concerned with the interaction between services as well as between service features as long as these interactions are implementation-independent. Avoiding undesired effects due to service and feature interaction is a major issue in telecommunications (Zave 1993).

SFs are mapped into Service independent Building blocks (SIBs), which are defined within the global functional plane (GFP) (ITU-T 1997, Q.1203). SIBs are the smallest building blocks in an IN, and are combined into concrete services or service logic programs (SLPs) by the global service logic (GSL).

The SIBs in the GFP are part of functional entities (FEs) that reside in the distributed functional plane (DFP) (ITU-T 1993, Q.1204). A SIB can be found in more than one FE, but it must be present in at least one. FEs provide the functional specifications that can be followed by specific IN implementations. Each FE may perform a variety of functional entity actions (FEAs), which, in turn, may be performed within different FEs. However, a given FEA may not be distributed across FEs. The communications between FEs takes place via information flows (IFs). Functional entities in the DFP include, among others, functions well known in modern telecommunication networks, such as the call control function (CCF), the service switching function (SSF), the service control function (SCF), the service data function (SDF) and the service resource function (SRF). The bottom plane of the INCM is the physical plane (ITU-T 1993, Q.1205) which models the physical aspects of an IN, including the detailed design of physical network elements, Physical entities (PEs), and communication protocols.

A short analysis of the CCF and SSF components is provided below, describing how IN functionality is implemented at the switching level. The basic call state model (BCSM) handles basic call state processing and provides a view of basic call states to the SSF. It includes points in call (PICs), which correspond to call states that might be of interest to an IN SLP, and detection points (DPs), which correspond to call states in which execution of a call can be transferred to an IN SLP. There is also a basic call unrelated state model (BCUSM), which models the call unrelated switching function (CUSF), and is

concerned with the call unrelated interaction between the user and the service logic.

The SSF implements the switching state model (SSM), an object-oriented finite state machine that represents IN call control processing in terms of IN states. The SSM detects call-processing events that should be reported to active IN service logic instances or should trigger new ones. In addition, the SSM provides the SCF with a view of the SSF and CCF call-control activities.

The IN Protocol Stack

IN is implemented on top of the SS7 signaling network protocol stack. Figure 2 shows the relation between the open system interconnection (OSI) protocol layers and SS7.

The three levels of the message transfer part (MTP) provide for reliable transfer of messages between signaling nodes. The basic telephony functionality with respect to signaling (establishment, supervision, and termination of switched network connections) is provided by the integrated services digital network (ISDN) user part (ISUP). Therefore, ISUP controls the circuits used to carry either voice or data traffic.

IN related protocols sit on top of the MPT layer. The signaling connection control part (SCCP) enhances MTP level 3 with connection-oriented and connectionless network services as well as with address translation capabilities. Transaction capabilities application part (TCAP) makes use of SCCP functionality to support end-to-end transaction-based services between the various nodes in a network through a query/response interaction. In OSI terminology, TCAP is a remote operations service element (ROSE) protocol.

The IN application protocol (INAP) defines the IN application layer messages exchanges between the functional entities of an IN (SSF, SCF, and SRF). INAP defines an operation type in relation to each information flow exchanged between two communicating functional entities. The arguments of INAP operations are the information elements defined for the corresponding information flow.

Although IN can be implemented in a variety of architectures, the next section describes the most typical IN implementation that can be found in the majority of

Figure 2: The IN protocol stack

Figure 3: Typical IN architecture (SMS = service management system)

modern networks. It involves a platform-based approach, in which the service control function (SCF) is implemented inside a dedicated network node known as service control point (SCP).

Figure 2 contains the network-to-network interface (NNI) signaling protocols. There is also the user-to-network interface (UNI) signaling functionality, which includes the Q.931 and Q.2931 protocols for ISDN and broadband integrated services digital network (B-ISDN), respectively. Intelligent networking in mobile networks implements the customized application for the mobile network enhanced logic (CAMEL) standard, which is also based on the INCM.

Physical Architecture

The IN architecture separates service logic from switching functionality; moreover, it realizes service provision

by means of signaling only, before any end-to-end voice or data-related connections are established for a call.

A typical IN architecture is shown in Figure 3.

Within an SS7 network, several switches are upgraded to service switching points (SSPs). SSPs implement the service switching function (SSF) and the call control function (CCF). Therefore, SSPs perform basic call control and, in addition, can distinguish between simple voice and IN-related calls. Once an IN-related call is detected, the SSP informs a dedicated node called service control point (SCP). The SCP implements the service control function (SCF), which is responsible for service logic execution. The SCP contains service logic programs (SLPs) appropriately composed of groups of SIBs. The respective SLP is invoked and, according to the service logic structure, the SCP instructs the service switching points (SSPs) on how to process the call.

The IN architecture also includes the intelligent peripheral. This is a node that implements the specialized resource function. The intelligent peripheral is responsible for the communication between the users and the service. It can be used for digit collection, message playback, and voice recognition.

The data needed by the service logic are stored in the service data point (SDP) which implements the service data function. Although the SDP was specified as an independent node, many commercial implementations integrate it with the SCP.

A typical IN architecture also includes nodes dedicated to service management and to service creation. The service creation environment (SCE) is a platform that enables the graphical composition of IN services out of SIBs, which appear as visual components within the SCE. Several software engineering techniques can be applied for the design and verification of IN services, involving various methods of formal specification (Prezerakos, Anagnostakis, and Venieris 1999; Steffen and Margaria 1999). A detailed discussion on the origins and the evolution of the IN concept and standards can be found in Magedanz and Popescu-Zeletin (1996).

INs provide a vast variety of telephony services, such as free phone, localized weather forecast, televoting, routing by time/day/month, outgoing/incoming call restriction, do-not-disturb service, and many more. The free phone service constitutes a good example of the basic functionality behind an IN service. Free phone services involve the dialing of a nationwide number, usually starting with the digits 800, which is consequently translated by the respective IN service to an ordinary telephone number. Initially, a subscriber dials the free phone number. The call arrives at the SSP, which analyzes the called number and discovers that it starts with the digits 800, indicating that it is an IN call. Call execution is suspended and the SSP asks the SCP for instructions. The SCP analyzes the query and invokes the free phone SLP. The service logic translates the 800 number into the respective ordinary telephone number by querying a table in the SDP, which contains the associations between 800 and ordinary numbers. Finally the SCP instructs the SSP to setup a connection with that number, call processing is resumed, and the dialog between the two nodes ceases.

Benefits and Limitations of the Traditional Intelligent Network Architecture

The introduction of the intelligent network was regarded as a major step forward for telephony, since it provided network operators with several advantages, such as vendor independency, fast time to market, and easy service customization. But like every technological evolution, IN brought risks together with the advantages.

First, IN gives the SCP a leading role in service execution, effectively turning it into a single point of failure. If the SCP goes down, the services are unavailable to the entire network until the SCP is up again. Therefore, IN requires networks to provide for resilience mechanisms to the platform as well as to the network layer. Viewed from this angle, the IN concept is essentially non-distributed. Another IN shortcoming derived from its telephony

heritage. IN was a concept well suited for networks providing voice and narrowband data transmission. During the beginning of the 1990s technologies such as asynchronous transfer mode (ATM) and fiber optics provided sufficient bandwidth for the transport of richer forms of information. Video and digital audio were paving the way for what is now known as broadband multimedia services. Although improved resilience was an issue that the technology available at that time could deal with, multimedia communication in broadband networks required an improved concept for service provisioning. An enhanced IN architecture was the evident candidate for such a purpose.

BEYOND TRADITIONAL INTELLIGENT NETWORKS

Intelligent Broadband Networks

The rise of multimedia services requiring multiparty and multi-point connections created the need for an architecture that would facilitate the provision of such services. The state of ITU standardization at the time could not cope with these requirements—e.g. the signaling capability set (SCS) 2.1 (under approval as late as 1997), supported only single connection, bidirectional point-to-point and unidirectional point-to-multipoint call/connections. Also, Internet-like architectures lacked the mechanisms for guaranteeing the quality of service (QoS) required by these services in contrast to other transport technologies available at the time, such as ATM. Evidently, the IN concept was perceived as an overlay architecture that would complement B-ISDN in multimedia service provision.

IN and B-ISDN integration was primarily investigated by the Advanced Communications Technologies and Services (ACTS) project INSIGNIA (IN and B-ISDN Signalling Integration on ATM Platforms). INSIGNIA (Prezerakos et al. 1998) was concerned with the definition and implementation of an intelligent broadband network (IBN) architecture by applying the IN concepts on top of the transport infrastructure provided by ATM technology using, where possible, standardized B-ISDN protocols. INSIGNIA replaced the functional entities in the distributed functional plane of the IN conceptual model, SSF, SCF, SRF, and SDF with broadband versions, creating the B-SSF, B-SCF, B-SRF, and B-SDF, respectively (Figure 4).

Figure 4: Functional entities of integrated IN/B-ISDN

The B-SSF also contains the broadband call control function (B-CCF) as well as the broadband call unrelated service function (B-CUSF).

Since IN services provided by this architecture were composed of multiple calls/connections and call unrelated associations (out-channel interaction between user terminal and service logic), a session management mechanism was imperative. To this end, INSIGNIA implemented an object-oriented session model for managing the complex topology of calls/connections and call unrelated associations. Session objects provided the B-SCF and B-SSF with a common view of each service instance. Moreover, the session model enabled the B-SCP to initiate call setups, a feature that was very useful for services such as multiparty broadband video-conferencing. It should be noted here that connection control in INSIGNIA involved the setup and termination of dynamic ATM connections. However, in the course of time, this has not been widely accepted, since ATM was ultimately perceived by the market mainly as a fast transport technology over permanent or semipermanent backbone network connections.

INSIGNIA also specified and implemented a broadband INAP (B-INAP) protocol for the communication between B-SSPs and B-SCPs and between B-SCPs and B-IPs. Broadband IN services were developed with the use of a commercial service creation environment enhanced with evolved versions of narrowband SIBs that were appropriately modified to support multimedia and multiparty requirements.

INSIGNIA made an important contribution to IN evolution because it proved that the IN concept could be enhanced in a cost-effective manner to support the demanding requirements posed by multimedia broadband services. It also introduced the term "intelligent broadband networks" (Venieris and Hussmann 1998), which gradually replaced plain IN within the research community. In terms of service distribution however, INSIGNIA retained the B-SCP as the central point of service logic execution. The rest of the article uses the IN term to refer also to intelligent broadband networks (IBNs).

Distributed Processing Technologies

At the beginning of the 1990s the widespread adoption of new software engineering technologies such as object orientation (OO) and component distribution started to affect the design and deployment of telecom services. These technologies provided for code reusability through software components that, although being distributed over heterogeneous platforms, could, at the same time, interact in a transparent manner. They also aimed at providing independence of application and service provision from specific hardware/software platforms. Two principal technologies in this area were the Common Object Request Broker Architecture (CORBA) (Object Management Group 2005) and the mobile agent technology (MAT). Eventually other similar technologies emerged such as the Distributed Component Object Model (DCOM) from Microsoft and the Java Remote Method Invocation (RMI) from Sun Microsystems. Both CORBA and MAT were immediately perceived as facilitators for the design and implementation of advanced services in fixed as well as

wireless networks (Venieris, Zizza, and Magedanz 2000). Evidently, the question arose about whether the IN model could be adapted in order to take advantage of both CORBA and MAT. Dynamically deploying mobile code into a network using agents was a concept well beyond the state of the art; therefore, the introduction of CORBA was perceived as a more conventional way forward.

CORBA

The CORBA standard was developed under the auspices of the Object Management Group (OMG) as a response to the requirement for a distributed object framework. CORBA specifies the rules and the architecture by which a system or an application can be created out of software components (or objects) distributed in multiple platforms that interoperate in a fashion that is transparent to both developers and users.

Interoperability is ensured because CORBA objects are required to expose to client entities a standardized interface that is implementation-independent. Object interfaces are defined with the interface definition language (IDL), and they are consequently compiled into the stub (or skeleton) interfaces, which is the actual code that describes the objects methods. IDL can be mapped to a variety of programming languages, including C++, Java, C, Smalltalk, and others. Clients use this interface to request services from objects or, in other words, to make calls to methods publicly available via the objects. Client requests specify a reference to the object, the name of the requested operation, and the respective operation parameters.

CORBA provides for ways to discover objects at the network level, to standardize the format of object references, and to encode messages required for inter object communication. These features are the responsibility of the object request broker (ORB), which is a dedicated middleware present in every CORBA-compliant platform. ORBs work in conjunction with object adapters to deliver requests to objects and to activate objects. The process of object activation also makes use of the implementation repository, which provides information such as the object's location and operating environment.

Besides static invocation via IDL, CORBA also allows the dynamic (at run-time) invocation of objects without compile-time knowledge of the respective interfaces. This is accomplished via the dynamic invocation interface at the client side and the dynamic skeleton interface at the server side. In this case, the information required for forming as well as serving a request (such as reference to the object, the name of the requested operation and the respective operation parameters mentioned above) is retrieved from the interface repository.

An overview of the CORBA architecture is presented in Figure 5.

At the network level CORBA specifies the general inter-ORB protocol (GIOP) for transporting method invocations and replies through the network. In the same manner that IDL can be mapped to a variety of programming languages, GIOP can be mapped to a variety of network protocol suites. The proliferation of TCP/IP networks has made the respective GIOP mapping to IP, known as the

Figure 5: CORBA architecture

Figure 6: A CORBA-enabled IN architecture (DPE = distributed processing environment/ SMF = service management framework)

Internet inter-ORB protocol (IIOP), the most popular inter-ORB protocol in the CORBA world.

Introducing Common Object Request Broker Architecture to Intelligent Network

The telecom industry saw in CORBA an interesting enabling technology for further IN enhancement. In particular, during 1996 and 1997, OMG issued a series of requests with respect to intelligent networking with CORBA (OMG 1996) as well as CORBA/IN interworking (OMG 1997).

Blending the CORBA model into an IN architecture requires that the following three issues are challenged:

- Interoperability with existing IN systems based on SS7
- Mapping of the IN event/trigger model to a relevant computing paradigm based on CORBA
- High performance, reliability and real-time support

An ideal CORBA-compliant IN, depicted in Figure 6, was envisaged as based on a distributed middleware platform comprised of nodes (SSPs, SCPs, SRFs, etc.) built out of CORBA objects on top of respective ORBs.

The nodes would be connected via a resilient network similar to SS7 but based on some GIOP mapping. Service invocations would originate from terminals at the network edges (fixed and mobile phones, computing devices, etc.) using the typical user to UNI signaling protocols such as Q.931 for N-ISDN or its broadband counterpart Q.2931 for B-ISDN.

CORBA-enabled SSPs translate these messages into object methods' invocations, which are consequently transferred to the CORBA-enabled IN nodes via IOP. The middleware architecture is complemented by several generic CORBA services, such as a naming service, and the generic CORBA event service as well as telecom-specific CORBA services such as a session-management service to handle the sessions established for the execution of different telecom services.

CORBA-enabled nodes would be able to use the IOP directly to communicate with one another. Non-CORBA-enabled nodes such as narrowband and broadband IN SSPs and SCPs would require a form of protocol conversion for communicating with the CORBA-enabled nodes. This functionality is provided by a dedicated network node, the CORBA/SS7 gateway. Such a gateway can be implemented with one of the three following options (Magedanz 1999):

1. **INAP/CORBA gateway:** In this case the gateway performs the conversion based on the mapping of INAP specifications into IDL-based interfaces. This mapping involves only IN services on top of TCAP; however, there are various INAP versions that deviate from the ITU-T standard. This is an interoperability problem that CORBA-based networks inherit from traditional IN.
2. **TCAP/CORBA gateway:** This is a more general solution for all TCAP/ROSE protocols (of which INAP is only one member along with e.g. MAP). The realization of a TCAP/CORBA gateway requires a conversion between resident operating system (ROS) constructs defined in abstract syntax notation One (ASN.1) and the corresponding CORBA structures expressed in IDL. This is a preferred solution, since it provides for CORBA interoperability with more application layer protocols than INAP.
3. **Using SS7 as an IOP:** This type of interworking, also called a "kernel transport network" (EURESCOM, 1997), allows distributed CORBA objects to communicate over the existing SS7 infrastructure by using SS7 as a transport mechanism. In AT&T, GMD FOKUS, IONA Technologies Plc, Nortel, Teltec DCU (2001) a GIOP mapping onto the signaling connection control part (SCCP) protocol of SS7 is defined for this purpose, which is called SCCP inter-ORB Protocol (SIOP).

The adoption of the distributed processing environment (DPE) principles in the telecoms world reached its peak with the consortium for a Telecommunications Information Networking Architecture (TINA). TINA (Barr, Boyd, and Inoue 1993) defined a framework for the development of service and network management applications in which service components are deployed on a distributed

processing environment (DPE), which can be implemented on top of different network infrastructures. TINA services are provided by means of the interaction of computational objects (COs) that contain logic and data and offer specific operations. The communication between COs is supported by the DPE that allows the arbitrary distributions of COs. Migration from IN to TINA was expected to take place gradually by "TINA-rising" the IN elements by means of COs on top of a DPE (Herzog and Magedanz 1997). Initially, the TINA DPE was based on the International Standards Organization (ISO) open distributed processing (ODP) framework (ISO/IEC 1996) and was later migrated to CORBA.

Obviously the transition to TINA was expected to lead an intermediate state in which there would have been islands of TINA-rised networks in parallel to the traditional IN architecture. In the context of TINA/IN interworking, the IBIS project (Listanti and Salsano 1998) implemented a gateway based on principles as similar to those of the INAP/CORBA gateway. The proposed gateway was called adaptation unit (AU) and contained the interworking object (IwO). On the TINA side, the IwO interacted with the TINA user application (UAP) objects, while on the broadband IN side, the IwO interacted with a simplified B-SCF that handled the dialog with the B-SSFs, terminating the B-INAP protocol. For the services handled by the TINA service logic, the B-SCF could not make autonomous decisions, relaying all B-INAP messages to the IwO. Similar approaches involving TINA-endorsed AUs were discussed within OMG's TINA-IN-Workgroup created in April 1998.

Dynamic Code Deployment

The intelligent network control architecture (INCA) discussed in (Isaacs and Mortier 1999) moved one step further in terms of distributing processing. INCA exploited the features offered by the Tempest environment to provide IN services that could not have existed in either narrowband or broadband IN architectures.

The Tempest environment allows the partitioning of resources in the switching elements into one or more virtual networks managed by separate control architectures. INCA uses Tempest for realizing IN services that consist of dynamically loaded code in the form of service scripts. Service scripts are disseminated to the various parts of an active control architecture and cooperate for the provision of a certain IN service. INCA introduced features from the domain of active networking to the IN concept. However, this happens in an architecture that used proprietary network interfaces to a significant extent. Similar approaches to the same problem adopted a more coherent approach by adopting an active networking technology known as mobile agent technology (MAT).

INTELLIGENT BROADBAND NETWORKS AND MOBILE AGENTS

Mobile Agents

Although general consensus does not exist on a definition of the term "software agent" (Bradshaw 1997), one can say

that an agent is an integrated software entity including code as well as data, with its own state, behavior, and with the ability to interact with other entities—including people, other agents, and legacy systems. Agents can be static, spending their entire life cycle within the same platform, or mobile, hence the term “mobile agent technology” (MAT). Services designed according to the MAT paradigm are composed of a set of mobile agents (MAs) that move from node to node inside a network. MAs can visit a node, execute several tasks, and then suspend execution and migrate to a new node, where their execution is resumed.

During service execution MAs can interact with other MAs in the same or a different node. MAT provides several benefits, such as autonomous task execution, reduction in network traffic due to local processing, automation of distributed processing, and increased resilience (Chess, Harrison, and Kershenbaum 1998). The most important aspect, though, with respect to service provision, especially for distributed IN, is the flexibility that MAs provide for on-demand service provisioning. Mobile agents can be used for the instant download of service segments to client and server nodes. Downloading and execution of MAs, however, requires a dedicated agent execution environment (AEE) or “agency” to be installed in the respective network nodes.

The obvious requirement for interoperability between agencies from different vendors as well as between agencies and several hardware/software combinations led to an international effort toward MAT standardization. This effort was undertaken by the Foundation for Intelligent Physical Agents (FIPA) as well as the OMG via a dedicated Agent Special Interest Group.

MAT became the core technology for service provision in wireline and wireless environments for numerous research projects (Raatikainen 1999). The following section discussed the results of the MARINE project, which combined MAT with CORBA to create a fully distributed intelligent broadband network (DIBN).

A Reference Architecture for Distributed Broadband Intelligent Network

MARINE (Faglia, Magedanz, and Papadakis 1999) expanded the broadband IN model in order to include the following innovations:

- Functional entities that controlled the exchange of service-related information (M-CUSF, SSF, SCF, and SRF) were developed using CORBA as a distributed processing environment (DPE).
- Several functionalities were consolidated in a single physical entity, thus creating a novel mapping of functional to physical entities.
- A computational model was defined that allowed CORBA objects to support IN services.
- Service logic programs (SLPs) at the SCP and at the intelligent peripheral level included service objects defined in the form of mobile agents.

In MARINE, switching and control functions are combined into SSCPs (service switching and control points),

which correspond to an integrated SSP/SCP and SENs (service nodes), which correspond to an integrated SSP/SCP/IP. Therefore, MARINE abandons the concept of a centralized SCP and suggests the use of multiple small-scale SSCPs and/or SENs in parallel. MARINE connection control also relied, like INSIGNIA, on dynamic ATM connection handling.

Service logic programs (SLPs) can be hosted either at the SSCPs or at the SENs. This is partly due to the fact that the SSF, SCF, SRF, and M-CUSF are CORBA compliant; therefore, communication between those FEs takes place via the IIOP (Internet inter-RB protocol) providing location transparency. No modifications are required at the terminals, since the MARINE architecture communicates with terminals via standardized user-to-network signaling.

MARINE also defines objects belonging to the functional entities hosted on the DPE and specifies the information flows between them. This computational model allows an IDL (interface definition language) specification of single CORBA components, which are used to provide IN services. The model in question includes two broad categories of objects, service-specific objects (e.g., implementing specific service features in SLPs) and architecture-specific objects (e.g., the object that corresponds to the switching state model).

A percentage of these service-specific objects exist in MARINE in the form of mobile agents. The use of mobile agents enables these objects to roam between the service execution nodes (e.g., from a B-SSCP to a SEN and vice versa), realizing in essence a dynamic deployment of services. The deployment of services can also take place via the download of service agents from a service creation/management system to B-SSCPs and SENs. The use of mobile code in the form of agents requires the existence of an AEE (agent execution environment) into the respective nodes of MARINE. The selected MA platform for MARINE was Grasshopper (Bäumer and Magedanz 1999). All AEEs form collectively a DAE (distributed agent environment) in which the service agents may roam.

Service Execution

The MARINE B-SS&CP

The MARINE switching platform was an evolution of the INSIGNIA B-SSP, which has been enhanced to include a Java virtual machine, an agent execution platform and a DPE based on CORBA.

Physically, the B-SSCP comprises two systems: A server that is in charge of handling the IN signaling and a switching ATM matrix for handling switched voice and data connections. An Ethernet bus connects the two systems, allowing the server to request from the switch the establishment, modification, and release of switched connections according to the signaling information.

Figure 7 presents the B-SSCP architecture; it is obvious that the base signaling stack (UNI, NNI, B-INAP, CUSM) has remained the same. In general, the MARINE B-SS&CP could communicate with a B-INAP-based B-SCP, allowing it to work with broadband IN.

The DPE cooperates with the switching part of the B-SSCP via an appropriately modified switching state model (SSM). Moreover, a mobility basic call unrelated

Figure 7: The MARINE B-SS&CP

Figure 8: The MARINE service execution node

state machine (M-BCUSM) has been introduced that detects triggers and events related to mobility functions such as user registration.

The MARINE Service Execution Node

The service execution node (SEN) resulted from the integration of the B-SCP and the B-IP used in INSIGNIA and EXODUS projects—EXODUS (Francis et al. 1998) was a project focused on the transition from second-generation to third-generation mobile networks, and as such it performed research on the specification and implementation of IN functionalities that met third-generation requirements.

Like the B-SCCP, the MARINE SEN has been enhanced with both an AEE and a CORBA DPE. The SEN

accommodates broadband IN functional entities (such as CCAF, B-SCF/SDF, B-SRF) as well as mobility-related functional entities (M-SCF/SDF). The SEN is shown in Figure 8, with the exception for the omission of the part that handles the communication with the subscriber's terminals.

The SEN establishes a switched connection with the terminal equipment (TE) in order to provide to the user the specialized resources required for the execution of a specific broadband service. The signaling communication between the SEN and the B-SS&CP is based on CORBA, specifically IIOP, or on the SS7 signaling stack for backward compatibility. In the latter case, a B-INAP-CORBA bridge is used. The MARINE SEN supports a B-INAP-based B-SSP, allowing the ability to work with

broadband IN. Also the SEN communicates with the service management system (SMS) via IIOP in order to serve management requests and service deployment—i.e. the downloading of agents from the SMS.

The AEE in the SEN enables the local execution of the various mobile agents that are part of IN services. Depending on various criteria that can be satisfied during service execution, agents can migrate to B-SCCPs or to other SENs. These criteria are monitored either by the SMS or by the agents themselves, which consequently may decide to migrate. Usually, agent migration takes place because of perceived performance degradation. For example, an agent executing within a certain SEN may experience performance degradation when several B-SCCPs attempt to access the same service at the SEN concurrently, thus inducing a high processing and communication overhead. Migration to a less-loaded node is the recommended solution in this case. Agents can also migrate in case of connectivity loss or when user mobility has to be accommodated.

Beyond MAT

MARINE realized the concept of the distributed intelligent broadband network by means of two core distributed processing technologies, CORBA and mobile agents. As a result, almost every node in such an architecture (with the exception of terminals) was required to host an ORB as well as an agent execution environment. Especially the latter was something quite uncommon to telecom operators at that time. An answer to this problem was attempted by developing the service logic with conventional methods and using mobile agents only for the implementation of code mobility.

DISTRIBUTED INTELLIGENT BROADBAND NETWORK IN THE ERA OF NETWORK AND SERVICE CONVERGENCE

This approach taken by the IN concept and its various evolved forms (IBN, DIBN) seemed adequate up until the late 1990s, when the demand for a new service provisioning model re-emerged for the following reasons:

- Deregulation forced many operators to open up their networks to third-party service providers.
- The foreseen saturation of the voice communication market (especially in mobile telephony) reinstated value-added service provision as a necessity for sustained revenue growth.
- Technologies originating from the Internet became adopted by traditional networks and started to threaten long-established services (e.g., traditional voice calls) because of low cost and increased simplicity.

The most immediate threat to traditional telephony originated from the Voice over protocol (VoIP) technology. VoIP allows for the transport of packetized voice over the Internet's network layer. VoIP implements its own call state model in the equivalent of traditional switches,

which are called "soft switches," since they are completely software-programmable. VoIP also incorporates signaling-like functionality by using dedicated application layer protocols. Recommendation H.323 (ITU-T 1998) and the session initiation protocol (SIP) (Schulzrinne and Rosenberg 2000) are two main frameworks regarding VoIP implementation and its interworking with PSTN. H.323 is a complex framework that specifies in detail a suite of protocols used for data, voice, audio, and video communication over IP. It also provides for specialized nodes, the gatekeepers, which map SS7 messages to the respective H.323 messages and vice versa. SIP, on the other hand, is an application-layer text-based protocol that is used only for session initiation, modification, and termination between two terminals. Again, when communication with the PSTN is required, a gateway is used for message translation. As of this writing, SIP seems to be gaining ground over H.323 because of SIP's increased simplicity in implementation.

This new reality called for a service provisioning framework that could satisfy the following requirements:

- Design and deployment of services that could be offered over multiple network technologies (fixed, mobile, wireless, etc.) with minimum modifications.
- Services should be offered either internally by the operator or externally by third-party providers without increased complexity in design and deployment.
- The time to market for these services should be minimized even further compared with IN.
- Services should be provided both via traditional networks as well as via the Internet with identical functionality.
- Services should be able to exploit both traditional networks as well as Internet resources during the same session.

Operators concluded that service provision would be simpler, cheaper, and faster if a high-level API could be offered to service providers that rendered the underlying network technologies transparent. Ideally, such an API would allow for one version of the service to be provided via any network or even across networks of different technologies. Such an API that stemmed from an international standardization effort is Parlay.

Introduction to Open Service Architecture/Parlay

The first activities regarding Parlay took place in 1998 by a group of companies including BT, Microsoft, Nortel, Siemens, and UtiCom, known as the Parlay Group. Their goal was to devise an API that would provide third parties with access to the network functions required for the creation and deployment of value-added services. Over the years, the Parlay Group has grown in popularity, and it currently has enlisted more than 10 full and more than 45 affiliate members.

Parlay (Parlay Group 2005) provides third parties with programming interfaces that are open, are language- and platform-independent, and include security provisions.

Thus, Parlay APIs can be supported on top of various middleware technologies, such as CORBA, DCOM, RMI, and simple object access protocol (SOAP). Parlay defines two roles in the process of service provision: the network operator and the application service provider (ASP). The network operator is typically perceived as deploying and operating the actual network infrastructure—e.g., switching and transmission equipment, access networks, etc. The ASP provides numerous networks with value-added services by gaining access to the network provider's resources via Parlay APIs. The services provided by the ASP are executed on respective application servers. The application servers become clients to one or more Parlay gateways, which reside at the network edge, offering service control functionality (SCF) to the client via the Parlay API. A high-level Parlay architecture is depicted in Figure 9.

In 2001, the Parlay standard was aligned with similar standards on OSA from the Third-Generation Partnership Project (3GPP) and became officially known as OSA/Parlay. The OSA/Parlay standard has currently reached version 5.0 and defines numerous APIs covering almost every aspect of mobile/fixed multimedia applications. The APIs that relate to call control and management, such as generic call control, multiparty call control, multimedia call control, and conference call control APIs are of particular importance for the provision of IN-like services.

The Role of Parlay in a Distributed Intelligent Network Architecture

Parlay in the context of the DIBN architecture was perceived as a solution for the provision of the so-called hybrid services—e.g., services originating from PSTN that require some sort of interaction with the Internet, or vice versa. A simple case of such a service is when a user would like to receive e-mails at his office about calls terminating at his home. This is not possible with any of the IN models presented so far; however, it can be achieved with Parlay. The following paragraphs describe this effort, which was undertaken in the context of the STARLITE research project.

The STARLITE Approach

The research effort undertaken within STARLITE (Chaniotakis et al. 2002) had the following goals:

- Retain the inherent flexibility of DIBN to move application code to various nodes in the network.
- Integrate the Parlay APIs with the DIBN concept.
- Exploit Parlay to realize service convergence between PSTN and the Internet by enabling the provision of “hybrid” services.

The STARLITE reference architecture is presented in Figure 10. It consists of the service creation environment (SCE), the service management system (SMS), the service switching and control points (SS&CP), and the Internet service node (ISN; not shown). The functionality of each entity is examined below.

Service Creation

Design, implementation, and testing of STARLITE service takes place via the SCE. Although the service provision models between PSTN and the Internet are significantly different, the SCE exploits the Parlay APIs in order to provide developers with a unified view of the network. The SCE consists of the SCE graphical user interface (SCE GUI) and the code generator.

The SCE GUI has been based on the rational rose (RR), which is a tool that allows the creation of system models that are based on the unified modeling language (UML). The RR's state diagram editor enables the initial description of services as finite state machines. The RR state diagram editor has been enhanced with several service independent building blocks (SIBs), which are represented within the GUI as shapes resembling specification and description language (SDL) constructs. The SIBs relate to the definition of methods that can be invoked from a service, to branching decisions as well as to the inclusion of Java code directly into an SLP. The SCE GUI produces a textual description of the service in XML, which is fed into the code generator.

Figure 9: High-level PARLAY architecture (POTS = plain old telephone service)

Figure 10: STARLITE reference architecture (CA = carrier agent; RA = receiver agent)

The code generator is a Java utility that makes use of the SLP's textual description to produce the final version of the service. The code generator provides its own GUI, which allows the developer to specify which service's textual description should be processed, as well as the triggering criteria for that service. These criteria are incorporated into the service code in the format of the appropriate Parlay data structure. Thus, the SCF components that are responsible for setting the triggers (detection points), can obtain this structure and arm the triggers via the invocation of the Parlay enableCallNotification method on the SSF. The output of the code generator is a Java application that can be compiled via a standard Java compiler.

Service Deployment

STARLITE inherits from DIBN the ability of an active service instance to migrate to the various network nodes. In contrast to MARINE, however, service logic is not implemented in the form of mobile agents, because this would have required mobile agents to implement Parlay interfaces. Instead, mobile agents are used for providing a carrier service for the uploading, transfer, and delivery of service instances to the various service control points.

Two types of agents are responsible for the implementation of code mobility, the carrier agents (CAs) and the receiver agents (RAs). The CA takes hold of a service instance via a common interface provided by the service base class. It is, however, totally unaware of the specific logic implemented by each service. Either the SCE or the

SCP (in the case of migration) can trigger the SMS to deploy a CA instance. Upon triggering, the CA is informed about the address of the node hosting the SLP to be transported and the address of the node for which the SLP is destined.

Consequently, the CA transfers the SLP from the host to the destination node. Upon arrival at the destination node, the CA has no means of unloading the service, since it cannot obtain references to the local DPE components. Instead it communicates with the RA, which is a stationary agent, hosted in the destination node's local AEE, with references to the local DPE objects. Therefore, the RA obtains the service instance from the CA and passes it for execution to the node's components.

Consequently, the service binds to network resources via the service logic manager (SLM), which obtains the service's triggering criteria from the SLP and passes them to the network side managers in a structure compatible with Parlay specifications. This way, a service may receive events from the local SSP.

In addition, the STARLITE architecture incorporates the Internet service node (Papadakis et al. 2004) which serves as a front-end for Internet users wishing to use PSTN services and for phone users wishing to invoke Internet services.

One of the obvious advantages of using Parlay as an overlay to the DIBN architecture is the interoperability between Internet and PSTN-originating services. The same problem was tackled via SPIRITS, a similar approach that will be detailed in the following section.

Figure 11: SPIRITS/PINT (PSTN and Internet networking) architecture

The Parlay/SPIRITS Approach

SPIRITS stands for “Service in the PSTN/IN Requesting Internet Service” (Faynberg et al. 2002). It supports services originating from the PSTN that require interactions between the PSTN and the Internet. In essence, SPIRITS allows SCPs to request the processing of IN services to be carried out on the IP network. The SCP is informed of the processing result and instructs the SSP accordingly on how to process the call.

The SPIRITS architecture consists of the SPIRITS client, the SPIRITS gateway, and the SPIRITS server. During an IN service invocation; the service request is transferred from the terminal to the SSF and from the SSF to the SCF. Consequently, the SCF forwards the request to the SPIRITS client, which in turn conveys the request to the gateway. The gateway converts the request to the SPIRITS protocol and forwards to the server, which performs the actual processing. The result is conveyed back to the SCF in the same fashion. Service invocations originating from the Internet are handled by the PINT framework (Petrack and Conroy 2000), which follows a philosophy similar to that of SPIRITS, including servers and gateways (Figure 11).

The Parlay/SPIRITS architecture proposed by Kozik, Unmehopa, and Vemuri (2003) replaces the SPIRITS server with a Parlay application server and turns the SPIRITS client into a Parlay-enabled node that can map INAP messages to Parlay-method invocations. Parlay parameters and methods are encoded in XML-based format and are transported as the payload of a SIP message from the SPIRITS client to the SPIRITS gateway. This way,

developers can code SPIRITS applications using Parlay APIs, thus liberating themselves from the complexities of the underlying network. The SPIRITS/Parlay approach, although it lacks the advantages provided by the mobile code capabilities, is an alternative to STARLITE in terms of “hybrid” service provision.

Distributed Intelligent Network and Java

Parlay did not constitute the only effort toward the standardization of a high-level service-provision API. The wide adoption of Java as a programming language as well as an application development framework in conjunction with its developers’ (Sun Microsystems) intention to promote it as a universal solution for both IT and Telecom gave birth to the Java API for integrated networks (JAIN).

JAIN (Tait, Keijzer, and Goedman 2000) defines a number of APIs for the provision of a wide range of value-added services over data, fixed, mobile, and wireless networks. As is the case with Parlay, JAIN promises service portability, network independency, open development, and telephony support. The JAIN service logic execution environment (JSLEE) constitutes the standard Java-based service platform. JSLEE exploits a set of JAIN APIs such as JSIP (Java SIP), JCC (Java call control), SAMS (server APIs for mobile systems), and mobile device management and monitoring (DM), creating a framework for service deployment over practically any network technology. These APIs are also known as resource adaptors 3 in JAIN terminology, since they interface the application logic with the underlying network resources.

JAIN can be viewed as a technology complimentary to OSA/Parlay. According to this perspective, the OSA/Parlay gateway is another JAIN resource adapter RA that interfaces the JSLEE with the IN architecture. There is also the contrary view⁰ that JAIN could possibly replace OSA/Parlay entirely as the framework of choice for open service provision.

Service Provision in Next-Generation Networks

In one of the first books on INAP-based Intelligent Networks, Jan Thörner (1994) included a section "The Term Intelligent Network will not be used beyond the 1990s." The reason given for this prediction was that by that time the IN concept would have become a commodity in commercial telecom networks. The author was correct in the sense that IN has indeed become a commodity, and therefore the term has ceased to become a buzzword when it comes to service provision. What could not have been predicted, however, was that widespread adoption of the Internet would initiate the process for the complete abolishment of IN as a service-provision architecture. Of course, IN represents a significant investment in networks today, and therefore it cannot be immediately replaced. But the time will come inevitably in the medium-term period.

The Internet architecture, in contrast to telephony, requires relatively simple routers and expects the intelligence required for service provision to be provided by hosts at the network edge. Developments in the past decade in all the layers of network technology (from physical up to the application) have initiated the gradual replacement of complex architectures in fixed and mobile networks by new-generation networking (NGN) architectures. There are several approaches to NGN by Open Mobile Alliance (OMA), 3GPP, W3C, the Parlay Group, and others. The common denominator in this transition is the existence of the Internet protocol (IP) as the prevalent protocol at the network layer for voice, data, and control information. Although few aspects of NGN have been currently standardized, future service-provision frameworks are expected to portray the following characteristics:

- Use of packet-based transfer mechanisms especially over IP
- Separated control functions for bearer resources, call/sessions, and services/applications
- Decoupling of service provisioning from specific network technologies via standardized APIs
- Decoupling of third-party service provision from specific operators via standardized APIs
- Service provision will be realized via distributed components
- Support for a wide range of services and information flows
- Support of user and terminal mobility
- Service-tailored QoS requirements

- Services will be context-aware and highly personalized
- New personalized services will be automatically composed out of existing services

Currently the Web services standard (W3C 2005) is gaining momentum as the enabling technology for distributed service provision in NGN. The Parlay Group has crafted a new set of specifications, termed Parlay-X, which realizes the Parlay functionality with the use of Web services. Moreover all major telecom equipment vendors have unveiled plans to work toward a new service layer architecture.

CONCLUSION

The IN concept has its own unique place in telecom history as the first attempt for a standardized service-provision framework in telephony. During the decades, it has successfully undergone several evolutionary cycles to comply with the requirements for broadband and distributed services. Distributed IN will continue to coexist with more modern service-provision frameworks until it will become obsolete as legacy architecture. In the meantime IN has managed to deliver the following very important lessons to the service engineering community:

- Control information, either as out-of-band signaling or in the form of a dedicated control protocol, can be exploited for service provision.
- Service provision should be cross-network, cross-platform, and dissociated from the underlying infrastructure.
- Service development is facilitated if service functionality can be grouped into high-level independent building blocks (SIBs) that can be distributed transparently across the network infrastructure.
- Code mobility can lead to increased performance and improve resource utilization in the network.

Unless a drastically different technology emerges, next-generation networks will surely be fully aligned with the above principles, which constitute the IN legacy to future service-provision frameworks.

GLOSSARY

Common Object Request Broker Architecture (CORBA): A standardized framework endorsed by the OMG (Object Management Group) that specifies the interaction between software objects in a distributed computing environment.

General Inter-Object Request Broker Protocol (GIOP): An abstract protocol for the communication of distributed objects in a CORBA architecture. GIOP can be mapped to various network layer protocols depending on the network technology used for connecting the distributed objects.

Intelligent Network (IN): An architecture, initially for the telephone network, in which the service logic for a call is located in a dedicated node outside the switch, allowing services to be added or modified independently of the switching equipment.

Intelligent Network Applications Part (INAP): The application layer protocol of the SS7 signaling stack. Used in the intelligent network architecture for the communication between service provisioning nodes.

Mobile Agent (MA): A piece of computer software that is able to move from host to host autonomously and continue its execution on the destination host.

Parlay: An open API for fixed and mobile voice and data networks.

Service Control Point (SCP): A resilient computer that enables operators to offer enhanced services by executing service logic programs that manipulate call connections and call-routing information. SCPs connect to signaling nodes called SSPs.

Service Switching Point (SSP): An enhanced switch that interoperates with SCPs for the provision of advanced services in an IN architecture.

Signaling System no. 7 (SS7): An international standardized suite of protocols that provide out-of-band signaling in the digital public switched network.

INTRODUCTION

The sheer convenience of smart cards has contributed to their becoming more and more prevalent in a number of sectors today. We use them to withdraw money, to make telephone calls, to access buildings, to pay for goods, and to authenticate ourselves to a computer.

The Arrival of Smart Cards

Banking needs were the main driving force behind the introduction of the smart card's ancestor, the credit card (Rankl and Effing 2002). The main objective was to protect payment systems against fraud. The first credit cards were quite simple, and only included information such as the card's issuer and the cardholder's name, and the card number was printed or embossed on the card. These systems relied on a visual verification for security (security printing and signature field, for example), and as a consequence, the security of the system relied mainly on the traders that accepted the card. Because of the payment cards, increasing popularity, it became evident that this was not enough to prevent the system from being defrauded. The first improvement appeared with the addition of a magnetic stripe on the back of the card. This allowed data storage in a machine-readable form, making it easier to process transactions. The identification of a cardholder was achieved either via a signature or a PIN (personal identification number). Even though magnetic stripe cards are still commonly used worldwide, they suffer from a crucial weakness: data stored on them can be read, deleted, copied, and replaced easily with appropriate equipment. One solution would be to allow payment only when transactions can be validated online, but this is not always possible because of the high cost of the necessary infrastructure and the low speed of such transactions.

Patents were filed in several different countries at the end of the 1960 and the beginning of the 1970s on the

idea of using plastic cards to carry microchips (Jürgen Dethloff and Helmut Grötrup in Germany, and Roland Moreno in France). In 1974, the first prototype appeared, which functioned as a memory card. Two years later, the first microprocessor card based on a Motorola chip was developed. However, many new problems had to be solved before manufacturing in large quantities with acceptable quality and prices enabled the smart card to become a viable product.

The French telecommunications industry saw this new technology as an opportunity to reduce fraud and vandalism in coin-based phone booths. In 1980, the French General Direction of Telecommunication replaced all French phone booths with new ones equipped with a smart card reader. To make a telephone call a "telecarte" was required. It was initially credited with a fixed number of units that were reduced depending on the cost of each call made.

The telecarte's success convinced banking organizations that the smart card could be used in payment systems. In 1985, French banks agreed on a common payment system based on smart cards, resulting in the "Carte Bleu." The idea has since spread all around the world and was adopted by Europay, MasterCard, and Visa International in 1994.

Smart cards have also been used in health care, transport, pay TV, access control, electronic purse, and identity applications, and the number of different uses is always increasing.

More recent developments have introduced different types of embedded tokens that are based on the same technology as smart cards. Some examples of these are: RFID (radio frequency identification) tags that are intended to act as a bar codes for commercial goods, and USB (universal serial bus) tokens (sometimes referred to as a "dongle") based on a secure microcontroller. The protocols will be discussed in terms of smart cards,

as this is the predominant type of secure embedded token.

The Different Types of Smart Card

Since their first appearance smart cards have been compared with personal computers. In fact, the more complicated smart cards have a central processing unit (CPU), an operating system, and different types of memory, exactly like a computer. To satisfy the different requirements of the various applications, a number of different types of smart cards are in common use.

Memory-only cards: Memory cards consist of memory that can be written to once. These are mainly used to decrement units previously stored in memory—e.g. prepaid phone cards.

Memory cards with logic: Data stored in this type of card are protected with some hardwired logic. Such cards can be reloaded with updated values, since they include a high counting capacity, and are commonly used for public telephony. The logic present in the smart card can have an embedded cryptographic algorithm with a state machine to control it.

Microprocessor cards: In this case a microprocessor is embedded into the card to manage and compute data. Such cards contain a dedicated program, often referred to as an operating system (OS), in the read only memory (ROM), which manages other memory areas, such as the random access memory (RAM) and non-volatile memory, or the EEPROM (electrically erasable programmable read only memory), where personalization data is usually stored. The amount of ROM and EEPROM is very small and is usually expressed in kilobytes. The amount of memory available in smart cards is increasing all the time as advances in technology allow more transistors to be included in the same surface area. Some chip manufacturers also propose different types of memories, such as external RAM and Flash, granting extra data storage areas.

Contactless smart cards: Such cards can be either based on a microcontroller or a memory chip. Communication is performed via an antenna glued inside the card's plastic body, rather than directly via metal contacts. The different types of contactless smart card use various different radio frequencies and protocols, depending on the requirements of the application. For example, some frequencies require a card to be within 10 cm and others allow a card to be a few meters from a reader. Contactless cards are usually used in applications that require a high flow and low reader maintenance—e.g. transport or identification applications.

Dual interface cards: These cards are able to communicate both in contact and contactless modes. Two types of product are available:

1. Cards with two chips—one being a normal smart card chip and communicating via the normal contacts and the second a contactless chip with its own specific communication interface. These chips are independent and are used for different applications.

2. Cards with one chip that have both interfaces integrated on the silicon, although the interfaces may be separated logically within the chip.

Dual interface cards are generally designed to support more than one application—e.g. access-control cards with transport ticketing or e-purse.

Tamper Resistance

One of the most important features of a smart card is its tamper resistance. This means that the secrets stored within the smart card—e.g. cryptographic/authentication keys—are protected from unauthorized access. There are various attack methods that can be used on smart cards, and other embedded devices, to attempt to access secret information. Some of these methods are described below.

Hardware Attacks

The chip used in a smart card can be removed from its packaging to allow access to the surface of the chip using hot, fuming nitric acid to remove the resin around the chip to be able to directly access the chip. The information held on the chip can then potentially be accessed by directly reading the values held in the chips, memory. In practice, this is only ever possible on the ROM values, and current countermeasures (both the technology used and the scrambling of the data addresses) render this method of attack nearly impossible. Other possible methods of attack include disabling chip features, such as a random number generator, or attempting to reverse-engineer proprietary parts of a chip. Some examples of this type of attack are described in Anderson and Kuhn (1996).

Side Channel Analysis

As the protocols and cryptographic algorithms that are generally implemented in smart cards have been subjected to peer review and rigorous mathematical analysis, other methods have been sought to extract key information. The first example of this was the use of the time taken to execute certain public key algorithms (Kocher 1996).

This was followed by a method of deriving key information by performing a statistical analysis of the power consumption during the execution of an algorithm, called differential power analysis (DPA) (Kocher, Jaffe, and Jun 1999), by exploiting the small variations in power consumption (shown in Figure 1). The different levels of power consumption correspond to different values of the

Figure 1: Overlaid acquisitions of the current consumption produced by the same instruction but with varying data

Figure 2: An example DPA trace showing the data dependence of the current consumption over time

Hamming weight of the data being manipulated by the chip under observation.

To attack a cryptographic algorithm, hypotheses can be made on portions of the secret key and the values of individual bits are predicted for a series of acquisitions. If a bit is correctly guessed for every acquisition, this can be made visible by using a statistical treatment on the acquisitions acquired. Figure 2 shows the DPA trace produced by correctly predicting the behavior of 1 bit of the output of the first S-box used in the DES algorithm (data encryption standard; Federal Information Processing Standards FIPS 46-3). The first peak corresponds to the output of the S-box; the four subsequent peaks correspond to the manipulation of the same bit during the P-permutation (a bitwise permutation used just after the S-boxes). An excellent tutorial on DPA can be found in Aigner and Oswald (2006).

Another example of a side channel attack is simple power analysis (SPA), which observes one trace or several to try to derive information by direct observation of the power consumption. The most well known example of this is against RSA (Rivest, Shamir, and Adleman 1978). If RSA is implemented using the square-and-multiply algorithm (Menezes, van Oorschot, and Vanstone, 1997) it may be possible to distinguish between the two functions that make up the algorithm, and therefore derive information on the key used. Examples of this are given in Joye and Olivier (2005).

Equivalent attacks can also be derived by observing the electromagnetic emanations generated by a chip while it is computing a cryptographic algorithm (Gandolfi, Mourtel, and Olivier 2001). Small probes can be used to acquire the electromagnetic emanations from a portion of a chip, allowing different results to be obtained.

Fault Attacks

Fault attacks are based on injecting a fault during the execution of a process in such a way that an attacker can derive information because of the effect of the fault. The first example of this type of attack was proposed against RSA when it is implemented using the Chinese remainder theorem (CRT) (DeMillo, Boneh, and Lipton 1997). The calculation of RSA using CRT involves calculating two modular exponentiations, and combining the results. This is a common optimization because it allows the calculation to take place about four times faster than directly calculating the modular exponentiation necessary for RSA. If a fault is injected in either of the exponentiations one of the primes used in RSA can be calculated by the computation of a GCD (greatest common

denominator). A report of an implementation of this attack and some countermeasures are presented in Aumüller et al. (2002).

This was followed by fault attacks in secret key algorithms, where faults in DES can be treated in the same way that a differential cryptanalysis would be conducted (Biham and Shamir 1997). An implementation of this is discussed in Giraud and Thiebaud (2004) and this principle has since been applied to other algorithms such as AES (Advanced Encryption Standard, FIPS 197), in which several different attacks have been proposed (Blömer and Seifert 2003; Giraud 2004).

Software Attacks

Initially, the embedded software on smart cards could not be modified (i.e., it did not allow code to be installed post-issuance). The potential for an attacker to mount a software attack was therefore limited. The attacks at the time were to try all the possible parameters for a service—i.e. to attempt all the possible valid application protocol data units (APDUs) for a given card. The aim was to try to find bugs, undocumented commands, or back doors that would allow an attack to be mounted. However, these kinds of attacks are quite inefficient because it is easy to remove the commands from an operating system (OS), and the number of possible commands is large. With modern smart cards it is possible to load software onto the smart card, in the form of applets, which has allowed for more aggressive software attacks. These are discussed in later sections of this chapter.

Countermeasures

There are numerous countermeasures that are used in embedded code to protect against the attacks outlined in this section. These vary from masking data to prevent the power consumption being visibly dependent with the values calculated (Chari et al. 1999), data randomization (Joye and Olivier 2005) to desynchronization techniques (Clavier, Coron, and Dabbous 2000). The design of new attacks and countermeasures for embedded devices is an area of vigorous research.

COMMUNICATION PROTOCOLS

There are various different communication protocols for the different types of smart card. This depends on the physical method used to communicate and the complexity of the device. All values given in this section are given in hexadecimal.

Smart Card Protocols

A smart card has five contacts that it uses to communicate with the outside world, defined in the ISO/IEC 7816-2 (International Organization for Standardization 1999). Two of these are taken by the power supply (usually 3 or 5 volts), referred to as V_{cc} , and the ground used to power the chip. Another contact is used to supply a clock, which is allowed to vary between 1 and 5 MHz but is usually set to 3.57 MHz. The remaining two contacts are used to communicate with the card. A sixth contact was originally used to provide a higher voltage to program the EEPROM (referred to as V_{pp}). This contact is no longer used, as this presented security problems if a smart card was unable change the values held in EEPROM (e.g., to decrement PIN counters). The layout of these contacts is shown in Figure 3.

One of the contacts used for communication is used to send commands to the chip in a smart card called the I/O. The protocols used to communicate with a smart cards are referred to as $T = 0$ and $T = 1$ and are defined in the ISO/IEC 7816-3 standard (International Organization for Standardization 1997). This section will describe both protocols, as they are nearly identical. The extra requirements of $T = 1$ are detailed where relevant.

The remaining contact is used to reset the smart card (there are two additional contacts defined in the ISO/IEC 7816-3 standard, but they are not currently used). This is a physical event (i.e., moving the voltage applied to this contact from 0 to 1) that will always provoke a response from the smart card and can occur at any time. The smart card will respond by sending an answer to reset (ATR) to the I/O contact, which is a string of bytes that defines the protocols the smart card can use, the speeds at which the smart card can communicate and the order in

Figure 3: The six different smart card contacts, only five of which are currently used (I/O = input/output)

which bits are going to be sent during the session (i.e., most or least significant bit first). The smart card can also return up to fifteen historical bytes that have no impact on the protocol, but can be used to identify and distinguish one product from another. In the case of the $T = 1$ protocol, this is followed by a checksum on 1 byte that can be used to verify the integrity of the ATR. At this point the reader can change the protocol being used, within the bounds defined in the ATR, by sending a protocol type selection (PTS) to negotiate the parameters of the communication.

Each byte sent to or from the smart card is comprised of up to ten events on the I/O line—i.e. up to ten movements from 0 to 1 volts or vice versa, as shown in Figure 4. The voltage applied to the I/O line is set to 3 or 5 volts by the smart card reader before the reset is applied, so that either the card or the reader can pull this down to zero by connecting it to ground. The process starts by either the card or the reader pulling the line to zero for one elementary time unit (ETU—a length of time defined in the ATR that by default is 372 clock cycles). The byte is then sent over the I/O, where each bit is present for 1 ETU; whether the least or most significant bit is sent first is dictated by the ATR. This is followed by a parity bit that can be used to check the integrity of the byte sent. This is followed by at least 2 ETUs with no event on the I/O before the next byte can be sent. If the receiving party sends a signal of 1 or 2 ETUs on the line during the 2 end ETUs, this means that the byte was not correctly received. The misunderstood byte can then be resent.

The $T = 0$ and $T = 1$ protocols are half-duplex protocols, which means that data can flow in only one direction at a time. The reader initiates all the commands, and the smart card can only follow the instructions that it is sent. Each command consists of 5 bytes as shown in Table 1.

Each command sent by the reader will provoke a minimum of a 2-byte response from the smart card within a certain time, called the “status word”. If the command has executed correctly, the status word will be 90 00, otherwise a value signifying an error is sent as defined in the ISO/IEC 7816-3 standard. If a smart card requires more time to process the command that it has been sent, it sends the value 60 on the I/O, known as a time request, that informs the reader that more time is required before the command can be terminated.

If data need to be sent to or from the smart card before the status word is sent, this is preceded by the procedure byte. This is a byte sent by the smart card to the reader that is equal to the INS byte of the command that signals to the reader that the smart card is ready to send

Figure 4: The signals needed to send a byte on the I/O, where the voltage can take the value applied to the V_{cc} or 0

Table 1: The Elements of an APDU Smart Card Command

Byte	Description
CLA	The first byte is the class of the command and defines the application. For example, the Global System for Mobile Communications (GSM) smart card application will always start with the CLA = A0.
INS	The second byte dictates the instruction being sent.
P1	A parameter byte that can be used to pass parameters for the command.
P2	A second byte that can be used to pass parameters.
P3	The last byte of the command is the number of bytes of data that will be sent or received by the smart card. The direction of the data is determined by the instruction that has been chosen. An alternative can be used in which 2 bytes are used for the length value to allow more data to be transferred.

or receive data. The data are then sent, and the card terminates the command with the status word. This is termed a transport protocol data unit (TPDU), and with the T = 1 protocol this process is followed by a checksum byte used for integrity purposes.

In general, a high-level approach is taken, and a user will use an APDU. This allows a user to assume that data can be sent and received from the smart card in one command. The bytes that can be sent to or from the smart card are summarized in Figure 5. The value for P3 is replaced with Lc (the number of inbound bytes) and Le (the number of outgoing bytes).

This means that it is possible for a user to request incoming and outgoing data in the same command. This

Reader command data:

CLA	INS	P1	P2	Lc	Inbound data	Le
-----	-----	----	----	----	--------------	----

Outgoing data sent by smart card:

Outgoing data	Status word
---------------	-------------

Figure 5: The structure of an APDU as defined in the ISO/IEC 7816-3 standard

is resolved at the TPDU level by breaking the APDU into two TPDUs. The first TPDU is a command that has data being sent from the reader to the smart card; the smart card then returns a status in which the first byte is equal to 65 (or 9F in the case of GSM cards) and the second byte is the amount of data waiting to be sent. This is followed by a get response (a specific TPDU in which the INS byte is set to C0) command that allows the data to be sent from the smart card to the reader.

Contactless Protocols

In a contactless device, a chip is embedded in a smart card or other device that contains an aerial that is used to communicate with a suitable reader. There is, therefore, only one path of communication between the chip and the outside world rather than one per contact. This aerial also needs to provide the clock and power supply to the embedded chip and enable the embedded chip to communicate with a suitable reader. A reader achieves this by emitting a varying electromagnetic field (a sine wave, referred to as a “carrier wave”) that induces a current in the aerial of the smart card, which is used to power the chip and provide a clock. The communication relies on changing the modulation of the carrier wave used to power and clock the embedded chip. There are two types of contactless smart card, which are used for different purposes because of the different electrical properties of the cards. These are referred to as “proximity cards” and “vicinity cards”.

Proximity Cards

The majority of contactless smart cards are proximity cards, which follow the ISO/IEC 14443 standard (International Organization for Standardization 2000). The signal used to communicate with the proximity card has a frequency of 13.56 MHz and a range of approximately 10 cm, and there can be numerous different smart cards within this range.

There are two types of card that can be used with this protocol, which are described as type A and type B. This determines the representation of data in the signal (i.e., the modulation) and the initialization method. The protocol for communicating with type A cards will be used as an example in this section. In contact protocols (see above) bits are sent across the I/O by changing the voltage from 0 to 1 or vice versa, but this is not possible with contactless cards. Instead the carrier wave emitted by the wave is modulated, as shown in Figure 6, although this does not represent a zero. Each bit is represented by the carrier wave being unmodulated and modulated for

**Figure 6:** The change in the modulation of the carrier wave used to communicate with contactless smart cards

equal periods of time, where the order dictates whether a 0 or 1 is being sent. This is used to detect collisions when several cards are trying to communicate at the same time.

Because the reader does not know how many devices are present with the field, it needs to identify each device. This is achieved by emitting a request (REQA) that will be received by all devices in the reader's field. Each device will respond synchronously with an answer to request (ATQA) that will include 32 bits that uniquely identify each device. If two cards are trying to send different values, this can be detected, as, for a given bit, the modulation will last for the length of a whole bit rather than half a bit. The reader can deal with this by applying a mask to the number used to identify each smart card—e.g. it can ask that only cards whose most significant bit is equal to 1 to respond. This can be continued bit by bit to uniquely identify one of the smart cards present. The reader will then select this smart card (a SELECT command) and send a command to halt the smart card (a DESELECT command), which tells it to ignore all further REQA commands unless reselected or removed from the field and replaced. This process is then repeated for the remaining smart cards. Once all the smart cards have been identified one smart card can be selected for further communication.

This process of identifying all the cards present within a reader's field is universal for all cards of the correct type. After this, a smart card will either respond to a proprietary protocol or a protocol referred to as $T = CL$. Once a card has been selected, it is sent a request for answer to select (RATS) and responds with an answer to select (ATS). The ATS serves the same purpose as the ATR described in the previous section, and defines the parameters of the protocols that are supported by the device. This can be modified by a protocol and parameter selection (PPS) that is equivalent to the PTS used in $T = 0$ and $T = 1$. After this, the reader and the device can exchange information in a transparent manner with a small header and footer. After the reader and the device have finished exchanging information the session is ended with a DESELECT command.

There are three predominant types of proximity card, as described below:

Radio Frequency Identification (RFID)—An RFID tag or transponder is an extremely small chip attached to an antenna. Unlike contactless smart cards the antenna is not set in a rigid plastic body, but is in a flexible sheet that can be stuck to any object. This tag responds to a contactless reader with an ID number that can be used to identify the object it is attached to. These data may also include other information, such as location information, product price, and date of purchase, etc.

Memory Cards—This is the most common type of contactless card, as most systems that use contactless cards do not require a large amount of processing power. One of the most common implementations of a proximity card is a MIFARE smart card (MIFARE 2006). These cards follow the anti-collision protocol defined above, but do not implement $T = CL$. The reader accesses areas of the chips, memory in either user or supervisor mode (with different rights to update or read different areas) using a proprietary protocol. All communication between

the reader and the MIFARE card is enciphered using a proprietary algorithm owned by Philips. These cards are often used in transport systems because of the low cost per card; some examples include the Octopus card in Hong Kong (Octopus 2006) and the Oyster card in London (Oyster 2006).

Microcontroller Cards—If a microcontroller is present in the device, the $T = CL$ is usually used as a wrapper to transport information. In the case of contactless smart card, the $T = 0$ or $T = 1$ protocol can be implemented within the payload of the $T = CL$ protocol. In this case the ATS replaces the ATR required by the $T = 0$ and $T = 1$ protocols.

Vicinity Cards

Another type of contactless device is known as a vicinity card, and is defined in ISO/IEC 15693 (International Organization for Standardization 2000). The difference between these and proximity cards is that the reader has a range of 1 to 1.5 m. These use a protocol similar to that of proximity cards, with anticollision and transmission routines, based on modulating the fluctuating electromagnetic field. These are a common alternative for RFID tags, as they allow for lots of tags to be evaluated without having to move each tag. Another example of the use of vicinity cards is access control—e.g. SKIDATA (SKIDATA 2006).

INTERFACING WITH SMART CARD APPLICATIONS

A user does not have to implement the protocols described in the previous section. Platforms have been developed that help a user by acting as intermediaries between an application and a terminal. Two examples of interoperable smart card terminal specifications are the OpenCard Framework (OCF) (OpenCard Workgroup 2005) and the Personal Computer Smart Card (PC/SC) (PC/SC Workgroup 2005). These proposals have reached a relatively mature state, but the market has not yet converged on a single proposal. Moreover, a new standard enabling access to smart cards on embedded devices, called JSR177, has appeared. In the following sections, an overview of these standards will be presented.

Personal Computer Smart Card (PC/SC) Specification

The PC/SC working group (PC/SC Workgroup) was formed in 1996 by a number of smart card companies in order to enhance the adoption of smart card technology. The main aim of the PC/SC group was the long-term improvement of interoperability between smart cards and terminals, along with the smooth integration of terminals into PCs running the Windows operating system. The first documents became public in December 1996 and are formally known as "Interoperability Specifications for Integrated Circuit Cards (ICCs) and Personal Computers." As a group these documents are referred to as PC/SC and are decomposed into ten parts (see Figure 7).

Figure 7: The PC/SC architecture Courtesy of PC/SC Workgroup, <http://www.pcscworkgroup.com/specifications/overview.php>

Part 1 provides a general introduction and an overview of the overall PC/SC architecture. Part 2 provides characteristics and interoperability requirements for compatible smart cards (defined as integrated circuit cards [ICCs]) and smart card readers (defined as Interface Devices [IFDs]). For example, it describes the low-level characteristics of the smart card and reader in terms of the lower transport protocol and error-handling procedures. Part 3 describes the interface to, and required functionality for, compliant IFD devices. These components enable the higher layers (e.g., the Resource Manager) of PC/SC to communicate with smart card readers in a completely independent and transparent way. Part 4 provides other low-level design considerations—e.g. protocols for communicating with PS/2 keyboards with integrated smart card readers.

The main component of the PC/SC architecture is the Resource Manager (described in part 5). This is the most important component in the architecture and mediates access to the smart card and reader. In general, it is responsible for “ICC and IFD resources, controls shared access to these devices, and supports transaction management primitives.”

Part 6 describes the service (e.g., ICC and Crypto) service provider models. The ICC service provider model offers all the necessary classes and context that will enable communication with a specific smart card. The optional Crypto service provider defines the necessary cryptographic functions that may be needed for accessing a smart card. Parts 7 and 8 contain advice on how to use the interface provided by the resource manager and how to handle information security operations (e.g., identification and secure storage) in a smart card solution. Parts 9 and 10 are considered recent additions to the overall PC/SC specification and contain information regarding the management of smart card readers with keypads

that can be used for PIN entry and secure PIN entry, respectively.

Implementations

Microsoft was the first member of the workgroup to develop an implementation of the PC/SC specifications for its operating systems. Initially, this was an external program that fulfilled the role of resource manager, described above, and a high level library, called the “SCard Application Programming Interface” (API). Now the resource manager is an integral part of all Microsoft’s operating systems (even Windows Mobile).

In the year 2000, David Corcoran and his colleagues initiated an open source project called “pcsc-lite” to provide better support for smart cards for the Unix-style operating system. The goal was to provide an implementation of PC/SC, and their efforts are gathered within MUSCLE (Movement for the Uses of Smart Card in A Linux Environment (MUSCLE)). In order to make transferring applications from Microsoft’s operating systems as easy as possible, the interface used for the SCard API was adopted. Today, “pcsc-lite” functions on a great number of platforms: Linux, Solaris, Mac OS X, BSD, HP-UX, etc.

Wrappers

In order to enable the programming of applications communicating with the resource manager in languages other than C++, wrappers have been developed that allow PC/SC functions to be called from other programming languages. These wrappers use the FFI (Foreign Function Interfaces 2004) mechanisms of these various languages. These wrappers currently exist for Perl, Python, Prolog, Ruby, and Java. The wrapper for Java, referred to as JPC/SC, is thus a direct competitor of the OpenCard Framework, which is discussed below.

- Support for cryptographic operations to enable payment protocols, data integrity, and data confidentiality
- A secure execution environment to deploy custom security features

An SE can be integrated into a variety of embedded devices. Smart cards provide a secure programmable environment and are the most widely deployed SE, and are used to deliver a broad range of security and trust services. These services can be continually upgraded with new and improved applications that can be installed on a smart card. They are widely deployed in mobile phones e.g. (SIM) cards in GSM phones. Alternatively, an SE may be entirely implemented in software on the J2ME device. The specification does not exclude any of the possible implementations of a SE, although some of the packages are optimized for implementation on a smart card.

The API in this specification is defined in four optional packages that can be implemented independently:

- *SATSA-APDU*—defines an API to support communication with smart card applications using APDUs.
- *SATSA-JCRMI*—defines a Java Card remote method invocation (RMI) client API that allows a J2ME application to invoke a method of a remote Java Card object.
- *SATSA-PKI*—defines an API to support application level digital signatures (but not verification) and basic user credential management.
- *SATSA-CRYPTO*—defines basic cryptographic operations to support hashing, signature verification, encryption, and decryption.

In short the JSR 177 provides two smart card access methods based on APDUs and a Java Card RMI protocol that allows a J2ME application to communicate with a smart card to leverage the security services deployed on it.

Comparison of the Architectures

The PC/SC architecture is the most deployed architecture across all the platforms. This is mainly because of the dominant position of Microsoft Windows, the open source implementation of PC/SC (pcsc-lite), and its adoption by Apple as reference implementation for their platforms. OCF is being used less and less, as the industrial consortium behind this standard no longer exists. However, JSR177 is a popular choice for embedded platforms, where the use of Java is well established. Table 2 gives a summary of the different architectures and the systems that support them.

MANAGING MULTIPLE APPLICATIONS

Multi-application smart cards are a relatively new development, and have made it possible to implement several applications and to dynamically load new ones during a card's active life. These applications do not run simultaneously, because the smart card operating system has only a single thread, but new standards are beginning to propose multithreading.

Multi-Application Platforms

The two main standards for multi-application smart cards are Java Card (Chen 2000; Sun Microsystems 2006) and MULTOS (MAOSCO 2006). Two new technologies have joined them with the birth of Smartcard.NET (Hive Minded 2006; SmartCard Trends 2004) and of the Multi-Application BasicCard ZC6.5 (ZeitControl 2006). Windows for Smart Cards (Jurgensen and Guthery 2002) by Microsoft can also be cited, although it appears to no longer be supported by Microsoft.

The architecture of a smart card implementing these technologies consists of an embedded OS that supports the loading and the execution of different applications. The OS provides a run-time environment with a virtual machine (VM) that provides security features (e.g., a firewall between applications and inter application data-sharing mechanisms). The applications are interpreted by the VM, which enables applications to be independent of the underlying hardware and thus promotes interoperability. The following sections provide an overview of the types of multi-application smart card.

Java Card

Java Card enables applications (so-called applets) written in the Java Card language (a subset of the Java programming language) to run on smart cards. This technology is standardized by Sun Microsystems and the Java Card Forum, who produce the Java Card specifications.

Java Card is developed in the Java spirit of “write once, run anywhere.” Java Card can support primitive data types such as `boolean`, `byte` and `short`, but not large data types such as `long`, `double` and `float`. Java Card supports one-dimensional arrays, packages, interfaces, and exceptions. Object-oriented programming paradigms are continued with support for inheritance, virtual methods, overloading, dynamic object creation, etc. However, not all the features are supported—e.g. strings, multi-dimensional arrays, dynamic class loading, security manager, and garbage collection. At the time of this writing, the

Table 2: Architectures and the Systems That Support Them

	Windows		Network Computing		UNIX/Linux/BSD		Others	
	Classical	Embedded	Classical	Embedded	Classical	Embedded	Classical	Embedded
C++								
Java								
Other								

Key:  PC/SC  OCR  JSR177

currently available Java Cards comply with version 2.2.2. In future versions, starting with Java Card 3.0, other features will be supported, such as multithreading and a TCP/IP stack.

MULTOS

The MULTOS operating system is mostly confidential, as it was developed from the Mondex system for electronic purses and is controlled by the industrial MAOSCO Consortium. For application development, MULTOS proposes MEL (MULTOS Executable Language), which is an optimized language for smart cards based on Pascal, and runs on a virtual machine described with a well-defined and fixed API (Watt and Brown 2000). Applications are typically developed in another language (e.g., C or Java) and then translated into MEL.

Smartcard.NET

Smartcard.NET was developed to support the .NET framework on smart cards. In the spirit of the .NET philosophy, the intention is to give the developer the freedom to select the most appropriate language for development while allowing different language applications to interact via a common library. Thus, the .NET applications can be written in C#, VB.NET, J#, Jscript.NET, J#, etc. The virtual machine supports all the types except floating-point numbers, code checking, 64-bit integers and remoting (called "RPC" in .NET). The API includes all the types and all the methods required by the language to support .NET (including strings). It also manages the I/O, cryptography, synchronization between threads, etc.

Multi-Application BasicCard

BasicCard has existed since 1996, although it is only since April 2004 that ZeitControl proposed its first multi-application card: Multi-Application BasicCard ZC6.5. Applications for this smart card are written in ZeitControl BASIC, which contains the majority of commands present in the traditional BASIC language, such as strings and the functions to handle them, arrays, data structures defined by the user, etc. One of the differences with the other technologies is that BasicCard is the only one that has native support for floating-point numbers. It also proposes a file system similar to FAT and an API to manipulate the file structure.

Windows for Smart Cards

Windows for Smart Cards (WfSC) was proposed by Microsoft (Jurgensen and Guthery 2002) in 1998 and is no longer in use; it is included here for completeness. This operating system had a real FAT file system and rule-based access control list. The proposed API was a considerably reduced version of the Windows (Win32) API. These cards could be used in a file system mode, with access via the standard ISO/IEC 7816 protocol, or a multi-application mode where applications could be downloaded. Applications could be developed in Visual Basic or Visual C++ using Microsoft Visual Studio.

Multi-Application Platform Attacks

A common problem of all open multi-application smart cards is the potential to load a malicious application that

would attack the security of the smart card. Such an application may attempt to:

- Identify available services on-card by collecting information and then trying to deduce the possible behavior of an official application (i.e., an application installed by some trustworthy organization, e.g. such as a banking application).
- Directly attack the VM and the firewall that is used to partition the resources between each applet.

The following sections describe how an attacker could attempt to attack a multi-application smart card.

Identification of Services and Collection of Information

The preliminary fundamental steps required to attack a card are the identification of the services that it offers and the collection of information regarding the OS and applications that have already been loaded. There are several ways that this can be achieved.

To identify the services offered by the card, any documentation is the first place to search for information. If this is not accessible, an attacker can try to load an application on the card to test every service defined in the specifications of the technologies supported by the card. For example, to identify the cryptographic services of a Java Card, an application can be loaded that uses `Cipher.getInstance` method (if the smart card supports the garbage-collection mechanism, this method can be called directly from anywhere in the code, otherwise the call should be inserted in the constructor). The application can be installed on the card and then be used to test whether the service is available with all the valid parameters, and then be removed to avoid any problem with an overflow in the heap due to multiple instances of the `Cipher` class.

If the smart card supports special mechanisms, similar to the GlobalPlatform management functions (e.g. the `Get Status APDU` command), the simplest way to collect information is to send the APDUs that reveal the required information. The attacker can also load an application on to a smart card to achieve this task. For example, to detect all the available applications on a Java Card and to determine whether they offer a service through the `Shareable` interface, all the possible parameters to the `JCSystem.getAppletShareableInterfaceObject` method can be exhausted. This particular method may return false negative results because of access control rules defined by the targeted application that determine whether services can be shared. If it is successful, and the attacker obtains `Shareable` interfaces, an attempt to apply illegal reference casting methods can be made (Montgomery and Krishna 1999).

Attacks against the VM and the Firewall

There exist many attacks directed against the VM and the firewall used in smart cards, but these are not covered here for brevity. Some attacks against the firewall mechanism, such as application identifier impersonation and illegal reference casting that provides access to all the interface methods of a class, are described in Montgomery

and Krishna (1999) and are based on type confusion. Some examples of attacks on the VM are described in Witteman (2003), and some attacks that are derived from problems in the specifications are presented in Betarte et al. (2002).

Mixed Hardware and Software Attacks

To improve the efficiency of attacks on a smart card, it is possible to combine fault and software attacks. Using one of the fault-injection methods, it would be potentially possible to create faults in the software running on the smart card (e.g., to bypass verification, or bypass firewall checks). These modifications of the normal behavior could also be exploited by a loaded application to access unauthorized services or information.

One problem of this type of attack is the precision required to induce a usable faults—i.e. finding the precise point during a command at which a fault could have the desired effect. To help in determining where a fault should be injected, some physical characterization methods can be attempted, as described in Chaumette and Sauveron (2005).

An actual implementation of this type of attack is presented in Govindavajhala and Appel (2003), where an attack is conducted against the VM of a PC using a lamp to induce faults by raising the temperature of the RAM being used to execute the applet. This does not apply to smart cards, as this attack requires a strict control of the addressing of subfunctions in RAM that are then accessed when a fault is induced in a function call.

Multi-Application Security Mechanisms

A verifier is often not included because of the limited processing power and memory available in smart cards. Consequently, it is often not advisable to run uncertified applications that may be provided by someone who wishes to attack the assets of a platform or the applications being run on that platform.

Verifier and Firewall

Several examples of on-card verifiers have published (Cohen 1997; Rose and Rose 1998; Leroy 2001; Barthe et al. 2002; Casset, Burdy and Requet 2002; Deville and Grimaud 2002; Leroy 2002), and they are starting to be included in Java Cards. Three of the solutions that have been proposed (the defensive VM, the verifier based on code transformation, and the stand-alone verifier) allow an application to be loaded without requiring it to be signed by a third party without jeopardizing the card security. This can permit anyone to freely load their own applications—i.e. anyone can still load a rogue application but it will eventually be rejected by the verifier or blocked by the defensive VM. The verifier based on code transformations (Leroy 2001, 2002) requires an off-card program to normalize the application, whereas the other two (i.e., the defensive VM [Cohen 1997] and the stand-alone verifier [Deville and Grimaud 2002] is stand-alone. The two approaches are equivalent (Barthe et al. 2002), but the defensive VM dynamically checks each executed bytecode, whereas the stand-alone verifier statically checks

the application once when the application is loaded, and it is associated with a VM that does not check the bytecode at execution time.

To enforce the security of multi-application smart cards, some other mechanisms have been added—e.g. the Java Card firewall. This firewall guarantees that each application loaded on to a Java Card is associated with a unique execution context, so that another application cannot access the objects created in this context. Exceptions can be created if explicitly stated in the application. This mechanism is orthogonal to the classical Java access rules.

Nevertheless, even though it is possible to have a real open multi-application smart card, issuers prefer to continue to support standards, such as GlobalPlatform (GlobalPlatform 2006), that enable applications to be securely managed on a smart card (as a set of cryptographic keys are required to authenticate a user before an application can be installed). This is likely to continue until the multi-application technologies are proven to be completely secure by formal methods. An example of this approach is the InspireD European project (InspireD 2006), which proposes modeling and verification tools that allow application developers to specify and to verify customizable security policies.

In the past, the FIPR (Foundation for Information Policy Research) thought that the multi-application cards were a bad idea, except in limited applications such as GSM SIM cards (Foundation for Information Policy Research 1999). Nevertheless, these cards are now a reality, even if they are currently available only as closed cards because of the constraints of GlobalPlatform. These open multi-application smart cards are not yet available on the market, but they are probably the future of smart cards because of the considerable amount of effort that is going into making them secure.

GlobalPlatform

International Visa initially developed the specifications of this standard within the Open Platform initiative, before being transferred to the GlobalPlatform consortium, where it is also supported by members of the banking and communications industries. The goal of the GlobalPlatform specifications is to bring a standard that, hitherto, was not present in the smart card arena: a specification to manage cards without any dependencies on hardware, manufacturers or applications. The actual GlobalPlatform specifications are related to the smart cards, the smart card terminals, and the global management of systems using smart cards. Only the on-card embedded GlobalPlatform architecture is presented in this chapter.

The GlobalPlatform card architecture is composed of a number of components that ensure hardware and vendor-neutral interfaces to applications and off-card management systems. GlobalPlatform does not mandate a specific run-time environment (RTE) technology and can be implemented on any multi-application technology. A user needs to conduct a mutual authentication with a smart card before applications can be loaded, so applications can be added only with the correct cryptographic keys for a given smart card.

Figure 9: The GlobalPlatform (GP) card architecture

Figure 9 shows the components in an example card configuration, which includes one or more applications from the card issuer; one or more applications from one of the business partners of the card issuer (referred to as “application providers”), and one or more applications providing global services (e.g., cardholder verification method services) to other applications. The card manager (a generic term for the card management entities of a GlobalPlatform card) acts as the central administrator for a GlobalPlatform card.

Security domains are important to the security of GlobalPlatform, as security management applications are used that ensure complete separation of cryptographic keys between the card issuer and other security domains (generally owned by application providers). Security domains support security services such as key handling, encryption, decryption, digital-signature generation, and verification for their providers’ (card issuer or application provider) applications. Each security domain is established on behalf of a card issuer or an application provider when these off-card entities require the use of keys that are completely isolated from each other. The applications interact with their related security domain via the GlobalPlatform API, which provides the aforementioned services (e.g., cardholder verification, personalization, or security services). GlobalPlatform cards may contain one or more trusted frameworks, which provide interapplication communication services between applications depending on the multi-application technology that the RTE implements (e.g., Sharing Interface Object of the Java Card technology).

APPLICATION SECURITY

The most common applications for smart cards are in the banking and telecommunications industries, where

smart cards play an important role because of their security functionality, combined with tamper resistance. The following sections give details of Third Generation (3G) and EMV (Europay, Mastercard, Visa) standards for use in mobile networks and the role that is played by smart cards in these systems. In the case of 3G, a brief history of how the security of mobile telecommunications has evolved is also given.

Third-Generation Network Security

The requirement for an application security solution for 3G solutions suggests that the second- and first-generation solutions were not entirely satisfactory. This is not meant as a criticism of the legacy systems, as security solutions were implemented based on the needs and perceived threats at the time. If the old analog TACS (total access communication system) can be taken as an example of a first-generation system, then its goal was to ensure that only people with a valid account could make calls and when they did they would pay for them. The fact that TACS offered mobile communication was regarded as a wonder of radio engineering, and security was never the highest-priority topic. The outcome was that there was no encryption of call transmissions, and the caller’s ID was simply their telephone number, which was also transmitted in clear. Confidentiality was therefore non-existent, and this led to some eavesdropping problems. However, there was at least an authentication method based on a serial number stored in the phone. An obvious problem was that the caller’s ID was transmitted by phone and so could not be regarded as a secret. The only defense was that a mobile phone’s serial number should only have been reprogrammed by authorized parties—but of course history has shown that this was not the case. The resulting escalation of phone cloning threatened to undermine mobile communication, and in a painful and practical way, taught the industry the importance of tamper-resistant security and confidentiality.

These lessons drove the European Technical Standards Institute (ETSI) to develop an enhanced solution for the new digital GSM system (referred to as second-generation [2G]), based on a tamper-resistant subscriber identity module (SIM) in the form of a smart card. The new protocols, underpinned by the SIM, supported confidentiality by using radio transmission encryption and temporary identities. Authentication was safeguarded by storing both a secret key (Ki) and an associated algorithm securely within a tamper-resistant SIM. The GSM solution has been very successful and has demonstrated the usefulness of tamper-resistant security modules; however, there are still some weaknesses. The priority with the 2G system was for users to reliably prove they had a valid account/SIM, so there was little consideration for the network to prove its authenticity to users. This led to the possibility of false-base-station or man-in-the-middle attacks that could also be used to turn off confidentiality measures. More widely known were attacks on the original authentication algorithm given as an example authentication algorithm called COMP128-1. It was a common misconception that COMP128-1 was “the” 2G authentication algorithm, as operators were free to develop and

use their own designs. While the more technically competent operators took this precaution, others opted for the example algorithm suggested by the GSM Association—i.e. COMP128-1. The algorithm was vulnerable to attack, and too much reliance was placed on keeping it secret. The outcome was that the design was leaked, vulnerabilities were discovered, and it became possible to clone some cards. This was exacerbated by the gradual emergence of low-cost but sophisticated side-channel attacks. The main lessons learned from the 2G-application experience were that mutual authentication was needed, that algorithms should be robust even when exposed to public scrutiny, and that sophisticated attacks on tamper-resistant modules were practical and must be countered. A final but no less important lesson was that if there is a disaster scenario when things go badly wrong, it is very useful to have a back up authentication algorithm or mode plus the administrative means to select it.

At the end of 1998 several working groups were launched to specify the security of the 3G system. The aim was to provide a replacement for the 2G GSM network protocols. Most documents issued by these work-groups are available online at the 3GPP Web site (3GPP 2004) demonstrating a commitment to openness rather than reliance on secrecy of specifications.

In a 3G network, mutual authentication is performed (i.e., both user and network have to authenticate to each other). This is the most sensitive operation in a 3G network, as it identifies the client for billing purposes. To initiate an authentication handshake, a challenge is sent by the network (the operator) to the USIM (the smart card supporting the 3G standards, equivalent to the SIM used in GSM) via the phone, which is considered untrusted. The challenge consists of a random 128-bit random number (RAND) and an authentication token (AUTN). Figure 10 presents an overview of the handshake protocol. The USIM will take the values supplied by the network and calculate a response (RES) and some session keys for ciphering and integrity (CK and IK, respectively) that are passed back to the mobile equipment (ME) and

the network. These values depend on a 128-bit key that is stored in the USIM and is known by the network. The response will also state whether the USIM was prepared to authenticate the network based on credentials supplied in the AUTN value, and assuming that this is the case, the network will then go on to check that the value for RES is the correct for the USIM in question.

The calculation of the RES value is done using an algorithm based on the AES (FIPS-197) called Milenage, although operators are free to replace this with a proprietary algorithm. The specification for this algorithm is also available on the 3GPP Web site, and the ETSI Security Algorithms Group of Experts (SAGE) group has made a “C” code version available. This represents a complete change in philosophy when compared to the 2G algorithms, which are still kept secret. The reason behind this is that the problems caused by COMP128-1 have left many network operators wary of trusting proprietary algorithms. However, each operator can customize Milenage (in a manner defined in the 3GPP technical report on the algorithm) so that a different version of the algorithm can be derived. This customization ultimately relies on global secrets, but only account-specific versions are stored within individual USIMs, and the operator can vary the customization across batches of cards.

Figure 11 shows the structure of the AUTN value sent by the network that contains the sequence number (SQN) (that may optionally be XOR (exclusive OR) -enciphered with the anonymity key [AK]), the 2-byte authentication

Figure 11: The authentication data sent to the USIM by the network

Figure 10: The 3G handshake protocol

management field (AMF), and the 8-byte message authentication code (MAC) field. These data are used by the USIM to authenticate the network as presented in Figure 11.

The AMF field is often overlooked, as it is not core to the description of the main 3G authentication process; however, it is important because it provides the means to control authentication. How it is used is not fully standardized, but a network operator could use it to select a backup algorithm or perhaps make changes to sequence-number generation. The MAC value is critical because it is used by the USIM to verify the authenticity and the integrity of the network supplying the authentication challenge. The algorithm for generating this depends on the values of RAND, SQN, AMF, and the secret key held in both the USIM and the network authentication center. This makes it difficult to trick the card into thinking that it is communicating with a valid network, unless the secret key is known. The SQN value is a sequence number that prevents message sequences being replayed, as the card will return an error unless a new SQN value is presented, and that varies according to parameters determined by the network operator.

The SQN generator scheme is not fixed, and it is possible to have time-based and non-time-based methods, providing that both the network and USIM know which method is in use. The security benefit of using sequence numbers is well established; however, there are some management issues to deal with, particularly the case of lost synchronization between a network and a USIM. When challenged with an invalid SQN the USIM will respond with the AUTS field, which is basically the USIM suggested SQN plus a MAC to confirm the information is sourced by the USIM. When only one network entity is involved, a basic sequence number and resynchronization mechanism is quite adequate. However, 3G systems are a little more complex, the network may generate small batches of authentication challenges/vectors for distribution to regional subsystems. Within a region a USIM might simply check for an incrementing SQN, if there is a change of region, an older, yet valid, challenge may be presented and rejected because of the SQN. To overcome this, the 3G specifications define the use of an array of sequence number checkers that are indexed by the least significant bits (typically 5) of the SQN field.

After an authentication algorithm has taken place, session keys (CK and IK) are used to provide confidentiality and integrity using an algorithm based on Kasumi (available in the 3GPP specifications). This algorithm is implemented in the mobile device, primarily for performance reasons. Although the mobile device is not regarded as a trusted device, the exposed session keys only have short-term significance, as they are regularly refreshed by the network using the USIM-based tamper-resistant algorithms and secret keys.

Because of the critical importance of the long-term secret key held in the USIM, the 3G standards also specify that the smart card implementations of the Milenage algorithm must be resistant to side-channel analysis such as SPA or DPA. The underlying fear is that because side-channel attacks are low cost, they must not under any circumstances permit an attacker to clone client cards and then use or sell them.

The 3G security application is interesting because of its sophistication and also because just about every feature is justified by the lessons learned from previous generations. The USIM (smart card) is at the core because of its proven tamper-resistant storage and processing capabilities when compared with mobile devices. The resulting solution is a sophisticated example of a symmetric security application, with mutual authentication, confidentiality, and integrity protection. It combines the openness of good algorithm design with the customization and management functions needed by network operators.

The smart cards also provide a mechanism of personalizing mobile devices that is totally under the control of the network operator. This means that subscribers can be provided with mobile devices made in the same factory but that are made individual by smart cards owned and managed by the operator. USIM cards could in fact be used directly or as a model for nonmobile network applications, as they provide proven methods for mutual authentication, personalization, and the distribution of session keys.

Europay, Mastercard, Visa (EMV)

The requirement for additional security, in the banking card industry, was realized in the mid-1990s when the three major financial institutions (Europay, Mastercard and Visa—hence the choice of the abbreviation EMV) decided to work together to capitalize on the underlying tamper-resistance benefits of smart card technology. The requirement for credit card fraud reduction was further enhanced in July 1996 with the release of a set of specifications, referred to as EMV 96 (EMV 1996). These standards cover a broad range of card characteristics (e.g., physical characteristics of the card, electrical signals to and from the card, etc.) along with the overall behavior of the credit and debit card resident applications. One of the goals of EMV was to further enhance the already existing credit/debit card architectures with the added functionality of additional on-card memory, processing power, and therefore, better risk management through online/offline authentication and authorization. In particular, the following processes are specified within the EMV standard:

- Offline PIN management
- Terminal/card risk management
- Online processing
- Card data authentication

Offline PIN management implies that, since the card offers tamper resistance, the PIN number can be verified by the underlying smart card microprocessor prior to a transaction being authorized. Terminal and card risk management processes ensure that both entities are provided with the necessary functionality that will enable it to decide when a transaction (e.g., high-value transactions or certain types of transactions) would go online for extra reassurance. For example, a card may decide to go online or even reject a transaction, always in line with the issuer's risk management policies. This will not only reduce communication costs for low value, and perhaps

“less risky,” transactions but at the same time offer the necessary reassurance.

Online processing is often described as the equivalent of the processing of magnetic stripe card transactions. The main difference is that the terminal can request from the smart card an application cryptogram (AC), which can be forwarded to the issuer in an authorization request message in order to further enhance the transaction authorization process.

With card data authentication the terminal verifies the authenticity of certain card resident data. The two main processes described in the standard are static data authentication (SDA) and dynamic data authentication (DDA).

The main aim of SDA is for the card to prove to the terminal that certain card resident data, and therefore the actual card, has not been changed. The whole process is fundamentally based on the existence of a certification authority (often run by the actual financial scheme—e.g. Visa, Mastercard, etc.). This entity maintains a highly secure cryptographic facility that is responsible for signing, with the scheme’s private key, the issuer’s public key. The corresponding scheme’s public key is placed in every card terminal conforming to the specifications. Subsequently, the issuer signs the aforementioned card resident data using the corresponding private key and

places this signature in the card during personalization. Subsequently, the scheme’s public key is used during verification to verify the issuer’s public key and to verify the card resident data. If the process is completed with no problems, the terminal obtains the necessary reassurance that the card data are genuine and have not been modified during the card’s lifetime. The actual process is described in Figure 12.

The DDA process is summarized in Figure 13. An EMV card capable of DDA also offers the aforementioned SDA process. The former is achieved using a unique private key that can be validated through a chain of certificates. More specifically, the terminal can receive a copy of the scheme’s (i.e., fulfilled by the role of the certification authority) public key, which is used to verify the issuer public key (contained within the issuer public key certificate). During the next step the terminal verifies the card’s public key by using the issuer public key (which is verified in the above step). The card’s public key is used in order to subsequently verify a challenge. During this process the terminal can challenge the card with some data and request a signature as a response. By using the above process the terminal will be in a position to verify the actual signature through the verification of the aforementioned certificate chain.

Figure 12: Diagram of static data authentication (Markantonakis and Rantos 1999)

Figure 13: Diagram of dynamic data authentication (Markantonakis and Rantos 1999)

It appears that the major financial institutions are fully committed to the EMV standards, and they provide financial, operational, and planning assistance to their member banks in order to migrate from magnetic-stripe card technology into chip card technology. The EMV standards indicate examples of cryptographic algorithms, cryptographic key lengths, and crypto periods, but the details of the exact key-management processes are left entirely to the actual scheme operators. As a result, all major financial institutions provide their bank members with the necessary guidelines. However, the migration from a magnetic stripe card base to chip card technology is not a trivial step, and it requires thorough planning and implementation. It is often the case that member banks do not possess the right skills and expertise to successfully quantify the potential benefits from such a migration. However, the smart card industry is also offering assistance to banks seeking to migrate. As a result, a large number of banks have gradually changed their credit cards to chip card technology. It remains to be seen whether the fraud levels have dropped to a level that will justify the investment.

CONCLUSION

An overview of the different protocols that exist for smart cards has been presented. There are also devices that function as secure tokens that have a USB interface. These devices are often used to provide copy protection for software, whereby, the software will not run without the device being present. These devices have not been covered in detail, as the implementations are proprietary and the USB protocol is beyond the scope of this chapter.

Some chip manufacturers also propose smart cards with a USB interface that will allow for a larger bandwidth between a smart card and reader (STmicroelectronics 2002). These chips include a USB interface conforming to USB 1.1, which has taken the form of two extra contacts on the smart cards micromodule that handle the USB communication. The specification of an example smart card chip can be found at STmicroelectronics (2006) based on ST Microelectronics's ST19 chip family. This capability would allow smart cards to be more versatile because of the increased bandwidth offered by the USB protocol. However, industry has found these cards inadequate to increase the bandwidth between a smart card and reader because of the complexity of the host interface (Praca and Barral 2001), although advances in technology may have rendered this view invalid.

A more recent initiative is the Secure MultiMediaCards (Secure-MMC) (Giesecke and Devrient 2005) that aims to blend smart card technology with MultiMediaCards (MultiMediaCard Association 2006). These chips aim to provide secure storage in devices, such as mobile phones, principally for digital rights management. The MMC standard allows for a bandwidth of up to 416 Mbps, depending on the clock frequency and the size of the bus used. It is assumed that a Secure-MMC will be able to decipher several megabytes per second on-the-fly (Praca 2005). It will also be able to store large amounts of content in a secure manner and provide the same protection that is currently seen in smart cards. The Secure-MMC is a relatively new technology, so no specifications are currently available.

Two of the most common uses for smart cards using the standards banking and telecommunications have been described, where the smart card acts as a secure token. Another common use of smart card technology is in transport services (Oyster 2006; Octopus 2006), although the implementation on a smart card is simpler than the examples presented above.

GLOSSARY

APDU: Application protocol data unit. A command in the T=0 or T=1 protocol that can consist of 1 or 2 TPDU's.

API: Applications programming interface. A set of pre-written, and often standardized, functions that can be used by developers.

EEPROM: Electrically erasable and programmable memory, used in smart cards to store data special to a particular smart card. This process is referred to as "personalization."

ETU: Elementary time unit. The number of clock cycles required to send 1 bit of information in the T=0 or T=1 protocol.

FAT: File allocation table. A commonly supported file system for computers developed by Microsoft for MS-DOS.

GSM: Global system for mobile communications. The most popular standard for mobile phones.

Hamming Weight: The number of bits set to 1 in a given bit string.

ICC: Integrated circuit card. A smart card.

IFD: Interface device. A smart card reader.

I/O: Input/output. Generally used to refer to the contact or pin used to pass information to or from a chip.

Micromodule: Term used to describe the chip used in a smart card when it has been attached to the metal plates that provide the contacts for communication and power supply.

PIN: Personal identification number. A four-digit number commonly used in smart cards to authenticate a user.

RAM: Random access memory. A fast access memory used in computers and smart cards alike to store variables and aid in calculation; it only holds its value while receiving power.

RFID: Radio frequency identification. A method of automatically identifying items by attaching a small tag or transponder that can communicate this identity using a contactless protocol.

RMI: Remote method invocation. A mechanism for invoking instance methods on objects located on remote virtual machines (i.e., a virtual machine other than that of the invoker).

RPC: Remote procedure call. Allows an application running on one platform to cause code to be executed on another platform.

RTE: Run-time environment. The implementation of a virtual machine that allows programs written for that virtual machine to run on a given platform.

S-Box: Used to refer to a substitution table in a cryptographic algorithm; these are a common feature of block ciphers.

TACS: Total access communication system. An early standard for mobile telecommunication.

TPDU: Transport protocol data unit. The basic command unit in the T = 0 or T = 1 protocol.

INTRODUCTION

The need for fault tolerance is becoming more evident as the complexity of digital systems continues to grow, with more and more transistors integrated on a single chip. With this development, the probability that some failure will occur is rising. It is hard to guarantee that the system is fault-free after production and testing, and that such faults will not occur later. Availability is also becoming progressively more important, as businesses continue to increase their reliance on information technology. Building fault-tolerant computer systems is now of paramount importance in many modern applications. In order for computers to reach a stage of acceptable dependability in the performance of modern applications, they must demonstrate the ability to produce correct results or actions in the presence of faults or other anomalous or unexpected conditions. Such fault-tolerant systems were first developed for robotics, process control, aerospace, and other mission-critical applications, for which the consequences of device failure could be catastrophic. Today, computers are playing a bigger role in everyday life and have left the clean environment of computer rooms for industrial and normal environments. They have to function normally even under many different environmental factors, such as temperature, humidity, electromagnetic interference, power supply, etc. Therefore, these systems have to be more robust and at the same time tolerate inadvertent user abuse. This coupled with the increasing complexity of modern computer-automated services demonstrates the need for ultra-reliable, highly available, fault-tolerant hardware and software. As hardware costs continue to decline and labor costs continue to escalate, the user cannot afford to have frequent service calls. To build fault-tolerant systems that can cope with the constant changes in environment and user requirements, it is essential to provide tools and techniques that enable developers to separate the concerns of fault-tolerant computing policies and mechanisms in applications.

FAULT-TOLERANCE TERMINOLOGIES

A computer system is generally constructed from a collection of software and hardware components, some of

which may fail from time to time. A *fault* is simply any physical defect, imperfection, or flaw that occurs in hardware or software. The fault is a source that has the potential to generate errors. A fault may be dormant or active; a fault is active when it produces an error. An *error* is the manifestation of a fault within a program, a data structure, a component, or a system. The error is part of the system state that is liable to lead to a failure. A *failure* occurs when the delivered services deviates from the specification. Failures are caused by errors. These concepts are very well defined in Nelson (1990) and Rennels (1984). Faults, errors, and failures can be further classified as *permanent* (continuous, stable, or simply an irreversible physical change), *intermittent* (occasionally present because of unstable hardware or varying hardware or software state, such as a function of load or activity), and *transient* (resulting from temporary environmental conditions). A fault/error *latency* is the length of time between the occurrence of a fault/error and the appearance of an error/failure due to that fault/failure. Failures can be of different types: *crash failure* (in which the system simply halts, but was working correctly until that time), *omission failure* (in which the system fails to respond to a request), *timing failure* (in which the response lies outside an acceptable time interval), *response failure* (in which the response is simply incorrect), or *Byzantine failure* (in which arbitrary responses are produced at arbitrary times).

Fault tolerance is the attribute that enables a system to achieve fault-tolerant operation. It is the ability of a system to continue correct performance of its tasks and respond gracefully to an unexpected hardware or software failure. A *fault-tolerant system* is one that can continue to perform its specified tasks in the presence of hardware failures and software errors. The key to fault tolerance is redundancy. *Redundancy* is simply the addition of information, resources, or time beyond that needed for normal operation of the system. Many fault-tolerant computer systems mirror all operations; that is, every operation is performed on two or more duplicate systems, so if one fails the other can take over. *Fault-tolerant computing* describes the process of performing calculations, such as those performed by a computer, in a fault-tolerant manner.

Dependability of a system is defined as the quality of service provided by the system (Laprie 1985). This definition

of dependability encompasses measures such as reliability and availability as distinct facets of a system specification. The *reliability* $R(t)$ of a component or a system is the probability that the component or the system will be operating correctly without failure in the interval from time 0 to t ; that is, $R(t) = P(T > t)$, $t \geq 0$. The component or system unreliability $Q(t)$ is then $1 - R(t) = P(T \leq t)$. If the time to failure random variable T has the density function $f(t)$, we can then compute the reliability $R(t)$ from the failure density function $f(t)$ as follows:

$$R(t) = \int_t^{\infty} f(x) dx$$

The availability, $A(t)$, of a system is defined as the probability that the system is available at time t . Different from the reliability that focuses on a period when the system is free of failures, the availability is concerned with a point in time at which the system does not stay at the failed state. It can be viewed as the percentage of time the system is available to perform its expected task. A system can have low reliability but have high availability.

The failure rate function $z(t)$, or hazard function, specifies the rate of the system aging. The aging process of electronic components typically follows the so-called bathtub curve (burn-in phase, useful life, and burn-out phase) as shown in Figure 1. There is a period when the failure rate is approximately constant—what is considered to be the useful life of the component. Intuitively, the *failure rate* is the expected number of failures of a type of device or system per a given time period.

If $f(t)$ follows an exponential distribution with parameter λ , then the failure rate function is constant (i.e., $z(t) = \lambda$), which corresponds to the useful life of the component. Here, the parameter λ is considered to be the failure rate. The reliability in this case is known to be an exponential function of λ and is given by $R(t) = e^{-\lambda t}$. An important relationship relating $z(t)$, $f(t)$ and $R(t)$ is that $z(t) = f(t)/R(t)$.

Usually, we are interested in the expected time to next failure, termed “mean time to failure.” The *mean time to failure* (MTTF) is defined as the expected value of the lifetime before a failure occurs. The MTTF can be computed from the reliability function as follows:

$$MTTF = \int_0^{\infty} R(t) dt$$

Figure 1: Bathtub curve

An important measure often used in maintenance studies is the mean time to repair (MTTR), or the mean downtime. MTTR is the expected value of the repair time, specified in terms of repair rate μ , which is the average number of repairs per unit time; that is, $MTTR = 1/\mu$. Another important measure in a repairable system is the mean time between failures (MTBF), which takes into account both MTTR and MTTF and can be computed as follows: $MTBF = MTTR + MTTF$. The maintainability $M(t)$ can be defined as the probability that the failed system can be restored to operation within time t . In terms of the repair rate, $M(t) = 1 - e^{-\mu t}$.

For a system with no possibility of repair, $A(t) = R(t)$. But, for a system with the possibility of repair:

$$A(t) = \frac{\mu}{\lambda + \mu} - \frac{\lambda}{\lambda + \mu} e^{-(\lambda + \mu)t}$$

In fact, we are mainly concerned with systems running for a long time. $A(t)$ has a simple steady-state or asymptotic expression. The steady-state or asymptotic availability A_{ss} is, therefore, given by

$$A_{ss} = \lim_{t \rightarrow \infty} A(t) = \frac{\mu}{\lambda + \mu} = \frac{MTTF}{MTTF + MTTR}$$

Coverage is defined as the ability of a system to perform fault detection, fault location, fault recovery, and fault containment. Coverage has two meanings: qualitative and quantitative. Quantitative coverage is concerned with how successful the recovery is from the specific type of failure, whereas qualitative coverage specifies the type of errors against which a particular scheme is meant.

Fault avoidance, fault masking, and fault tolerance are three main design philosophies to combat faults. *Fault avoidance* deals with ways to prevent, by construction, fault occurrence. It includes design reviews, component screening, testing, and quality-control methods.

Fault masking deals with ways to prevent faults from introducing errors. Triple modular redundancy (TMR) or majority voting and error correction in memory are some well-known fault masking techniques. *Fault tolerance* deals with ways to provide service complying with the specification in the presence of faults. It is achieved through redundancy in hardware, software, information, and/or computations. Fault detection, fault location, fault containment, fault recovery, and reconfiguration are typical methods. *Fault detection* is the process of recognizing that a fault has occurred. *Fault location* is the process of determining the location of the fault. *Fault containment* is the process of preventing the fault from propagating throughout the system. *Fault recovery* is the process of regaining operational status after the fault has occurred. *Reconfiguration* deals with eliminating a faulty unit from the system and restoring the system to some operational state.

MODELING FAULT-TOLERANT SYSTEMS

The modeling of fault-tolerant systems is primarily concerned with predicting system reliability and availability. A reliability model represents a clear picture of functional

interdependencies, providing a means to trade off design alternatives and to identify areas for design improvement. System designers evaluate alternative architectures for their applications in terms of cost, performance, reliability, availability, or combinations of all of these. Reliability models can be used to help set and interpret system reliability requirements, predict the reliability of different system configurations, identify reliability bottlenecks (weak points) early in the product life cycle, and determine cost-effective sparing and maintenance strategies. Most reliability-modeling techniques are based on reliability block diagrams based on a combinatorial method, Markov chains, fault trees, etc. Detailed discussion on these models can be found in Shooman (2002) and Siewiorek and Swartz (1998). In this section, we will simply review the two most popular methods: combinatorial and the Markov approach.

Combinatorial Approach

Combinatorial models use probabilistic techniques to enumerate the different ways in which a system can remain operational. The reliability of a system is generally derived in terms of the reliability of the individual components of the system and the way the components are interconnected. Series and parallel systems are the two most commonly used models.

Series System

In a series system, each component of the system is required to operate correctly for the system to operate correctly. The reliability of the series system can be calculated as the probability that none of the components will fail. Another way to look at this is that the reliability of the series system is the probability that all of the elements are working properly. Consider the series system consisting of N components as shown in Figure 2.

Suppose that each component i satisfies the exponential failure law with failure rate λ_i , such that the reliability of each component is $R_i(t) = e^{-\lambda_i t}$. The reliability $R_s(t)$ of a series system is then

$$R_s(t) = R_1(t) \cdot R_2(t) \dots R_N(t) = \prod_{i=1}^N R_i(t) = e^{-\sum_{i=1}^N \lambda_i t}$$

Note that the failure rate of a series system can be calculated by adding the failure rates of all the components that make up the series system.

Parallel System

In a parallel system, on the other hand, only one of several components must be operational for the system to be operational. Figure 3 shows the block diagram of a parallel system consisting of N components.

Figure 3: A parallel system

It is easier to compute the reliability of a parallel system by computing its unreliability first. The unreliability $Q_p(t)$ of a parallel system is the probability that all components will fail. In other words, $Q_p(t) = Q_1(t) \cdot Q_2(t) \dots Q_N(t)$. The unreliability $Q_i(t)$ of the component i is simply $1 - R_i(t)$. Thus, the reliability $R_p(t)$ of a parallel system can be shown to be

$$R_p(t) = 1 - Q_p(t) = 1 - \prod_{i=1}^N Q_i(t) = 1 - \prod_{i=1}^N (1 - R_i(t))$$

It should be noted that the equations for the parallel system assume that the failures of the individual elements that make up the parallel system are independent.

The generalization of a parallel system is the M -of- N system, in which there are N identical modules out of which M modules are required to work correctly for the system to be operational. The reliability of the M -of- N system is given by

$$R(t)_{MN} = \sum_{i=0}^{N-M} \binom{N}{i} R_m^{N-i}(t) (1 - R_m(t))^i$$

A good example of the M -of- N system is the TMR system, which, in particular, is a 2-of-3 system with reliability $R_{TMR}(t) = 3R_m(t)^2 - 2R_m(t)^3$.

Combinatorial models are simple and can be used as long as the system block diagrams are in series or parallel form, for which we already have the reliability expression. Computer systems, in general, are very complex. We rarely come across systems whose components are either in series or in parallel; rather they come in a combination of both (series-parallel or non-series-parallel), in which case the system block diagram needs to be broken down into smaller series and/or parallel systems before combinatorial models can be applied. Combinatorial models are not suitable for modeling repair but it is possible to incorporate coverage. To see how coverage can be incorporated, consider a simple parallel system with two identical units U_1 and U_2 as shown in Figure 4. The secondary unit U_2 is switched on in the event of the failure of the primary U_1 , if the system is able to detect the fault in U_1 .

Figure 2: A series system

Figure 4: A simple parallel system (standby sparing)

Assuming that C_1 is the fault coverage of U_1 , the reliability of this parallel system is given by $R_p(t) = R_1(t) + C_1(1 - R_1(t))R_2(t)$, where $R_i(t)$ is the reliability of unit U_i . Notice that in case of perfect coverage ($C_1 = 1$), we have $R_p(t) = R_1(t) + (1 - R_1(t))R_2(t) = 1 - (1 - R_1(t))(1 - R_2(t))$, which is the expression for a perfect parallel system. If $C_1 = 0$, $R_p(t)$ reduces to the reliability of a single unit (i.e., a simplex system).

Markov Approach

Markov modeling provides a systematic means of investigating system reliability for large and complex systems. One of the most significant advantages of the Markov models is that they allow us to model repair and coverage easily. Two main concepts of the Markov model are states and state transitions. The *state* describes the system at any given time with respect to component failures and the behavior of the system's redundancy-management strategy. Transitions govern the changes in state that occur in a system. Transitions from one state to another occur at given transition rates, which reflect component failure and repair rates. In this model, we calculate the probability of the system being in various states as a function of time. These state probabilities are then used to compute performance measures such as reliability and availability. For reliability modeling, we can use a first-order Markov model in which the present state depends only on the previous state and the state transition probability. Markov models can be of two types: discrete time and continuous time.

A set of differential equations define what is called a "continuous-time Markov model" (which is commonly used). This model can be solved to find the state probabilities. One of the most significant advantages of the Markov models is that they allow us to model repair and coverage easily. A major disadvantage is that the state space can grow exponentially with the number of components. We, therefore, need to find ways (such as grouping states, making assumptions, and/or simplifications) to render this problem tractable in many situations.

To illustrate the use of continuous-time Markov model, consider a simple redundant system with two identical components with failure rate λ and repair rate μ . The system is in operational state when both the components are operational, in half-operational state if one of the components has failed, and in failed state if both components have failed. Let P_O , P_H , and P_F denote the state probabilities; that is, the probability of the system is in operational state, half-operational state, and failed state, respectively. The state diagram for the Markov model is shown in Figure 5, assuming that we have perfect coverage and a single repair person.

The set of simultaneous differential equations (also called Chapman-Kolmogorov equations) that describe the system are given by

$$\begin{aligned}\dot{P}_O(t) &= -2\lambda P_O(t) + \mu P_H(t), \\ \dot{P}_H(t) &= 2\lambda P_O(t) - (\lambda + \mu)P_H(t) + \mu P_F(t), \\ \dot{P}_F(t) &= \lambda P_H(t) - \mu P_F(t).\end{aligned}$$

These equations can be solved using LaPlace transform with initial conditions $P_O(0) = 1$, $P_H(0) = 0$, and $P_F(0) = 0$ to obtain $P_O(t)$, $P_H(t)$, and $P_F(t)$. To get steady-state probability, we do not need to solve the differential equations. Instead, we solve the following equations to get P_O , P_H , and P_F :

$$\begin{aligned}2\lambda P_O &= \mu P_H, \\ (\lambda + \mu)P_H &= 2\lambda P_O + \mu P_F, \\ \mu P_F &= \lambda P_H, \\ P_O + P_H + P_F &= 1.\end{aligned}$$

Thus, we have:

$$\begin{aligned}P_O &= \frac{\lambda^2}{2\lambda^2 + 2\lambda\mu + \mu^2}, \\ P_H &= \frac{2\lambda\mu}{2\lambda^2 + 2\lambda\mu + \mu^2}, \\ P_F &= \frac{2\lambda^2}{2\lambda^2 + 2\lambda\mu + \mu^2}\end{aligned}$$

The Markov technique can be used to model imperfect coverage. If we consider a coverage factor of C for the above example, the state diagram takes the form shown in Figure 6, where the arc from "Operational" to "Failed" represents a single component failure for which the fault-tolerance features cannot successfully reconfigure.

Figure 5: Markov model for a redundant system

Figure 6: Markov model with coverage for a redundant system

FAULT-TOLERANCE TECHNIQUES

The key ingredient in all fault-tolerance techniques is redundancy. The redundancy may take several forms, including redundancies in information, hardware, software, and time. These techniques are summarized in this section. Detailed descriptions of various fault tolerance techniques can be found in Johnson (1989), Lyu (1995), Guerraoui and Schipper (1997), Pradhan (2003), Randell and Xu (1995), Hecht and Hecht (2003), Koo and Toueg (1987), Avizienis (1985), Torres-Pomales (2000), Nelson (1990), and Rennels (1984).

Hardware Redundancy

Hardware redundancy is the physical replication of hardware for the purpose of detecting and tolerating faults. This is perhaps the most common form of fault tolerance used in systems. A common form of this redundancy is the triple modular redundancy (TMR). In the TMR system three identical units perform identical functions, and a majority vote is performed by a voter on the output with the purpose of masking any single fault, as illustrated in Figure 7.

The general form of TMR is the N -modular redundancy (NMR). The voter in this scheme is, unfortunately, the single point of failure. In the case of NMR, N must be odd and such a system can tolerate $(N - 1)/2$ faults. The primary trade-off in NMR is the fault tolerance versus the hardware required. Power weight, cost, and size limitations very often determine the value of N in the NMR system. Other forms of hardware redundancy involve incorporating fault detection and fault recovery into the system at the expense of eliminating fault-masking capability. An example of this is the standby replacement. In this configuration, one unit is operational while one or more units are standbys. Various error-detection schemes are used to determine when the online unit has failed; if a failure is detected, the online unit is removed from operation and replaced with a standby. Hardware redundancy

can be categorized in three schemes: *passive (static)*, *active (dynamic)*, and *hybrid*.

Passive (static) schemes use fault masking to hide the occurrence of faults and prevent the faults from resulting in errors. They rely on voting mechanism to mask the occurrence of faults. Passive redundancy schemes instantly correct errors and do not require higher system-level intervention to do so. The TMR and error-correcting codes are some examples of the static redundancy scheme.

Active (dynamic) schemes, on the other hand, achieve fault tolerance by detecting the existence of faults and performing some actions to remove the faulty hardware (using fault detection), fault location, and recovery. Active schemes require interruption of system availability while the fault is isolated. Once the fault is isolated, the redundant resource is switched on, and the system is recovered. For a real-time system, if the error occurs in the middle of an operation, some program rollback is necessary to discard the bad data and to recover as much good data as possible. The primary advantage of dynamic redundancy techniques is that they can be implemented with fewer resources. Examples of active redundancy are duplication with comparison, standby sparing, and watchdog timers. In duplication with comparison, if two processors disagree on the result found for the same job, obviously there is an error. The disadvantage of this technique is that if both results are incorrect, the error will go undetected. Another disadvantage is that the comparator may be faulty and signal an error when both results are correct.

In the standby sparing technique, one module is operational with one or more modules used as spares. When an error is detected in the operational module, it is removed from operation and is replaced by one of the spares. In hot standby sparing, spare modules operate in synchrony and are prepared to take over at any time. In cold standby sparing, spare modules are not powered until needed to replace the faulty module. An example of standby sparing is illustrated in Figure 4. Watchdog timers are one form of active redundancy used for detecting faults in a system. The idea of watchdog timers is that a lack of

Figure 7: A TMR system

Figure 8: N-modular redundancy with spares

action indicates a fault. The timers may erroneously signal a fault if the module is slower than usual. The reason is that watchdog timers do not see any incoming results.

Hybrid schemes combine attractive features of both passive and active techniques. Static redundancy provides error masking and detecting capability. Dynamic redundancy provides a set of spares and a switching network for reconfiguration. Fault masking is used in hybrid systems to prevent erroneous results from being generated. Fault detection, location, and recovery are also used to improve fault tolerance by removing faulty hardware. This is a very expensive form of redundancy scheme to implement, and it is often used in critical applications, in which high reliability must be achieved. Examples of hybrid redundancy are N -modular redundancy with spares, self-purging redundancy, and triple-duplex architecture. The idea of N -modular redundancy with spares is to provide a core of N modules arranged in a voting configuration with additional spares to replace faulty units. A frequent configuration is three (redundant) modules with one or two spares. Figure 8 illustrates the operation of N -modular redundancy with spares. The self-purging redundancy approach is similar to the technique of N -modular redundancy with spares. The difference is that all units are active (no spares) at the same time. In this technique, each module can remove itself from the circuit if its output disagrees with the voted output of the system. This approach provides more fault tolerance but is more expensive as far as power consumption is concerned.

Triple-duplex architecture combines duplication with comparison and TMR. The use of TMR provides fault masking. The use of duplication with comparison allows for faults to be detected and then have faulty units removed from the system. In this configuration, each module of the TMR is duplicated (with a comparison scheme).

Information Redundancy

Information redundancy is concerned with the addition of redundant information to allow fault detection, fault masking, or possibly fault tolerance. Error-detecting and

error-correcting codes (ECC Page 2002; Lin and Costello 1983) are good examples of information redundancy. Error-correcting codes enable data to be sent through a noisy communication channel without corruption. To accomplish this, the sender appends redundant information to the message, so that even if some of the original data are corrupted during transmission, the receiver can still recover the original message intact. Many computers now have error-correcting capabilities built into their random access memories; it is less expensive to compensate for errors through the use of error-correcting codes than to build highly reliable integrated circuits. Storage devices (compact disk, random access memory, dynamic random access memory), mobile communication (cellular telephones, wireless, microwave links), satellite communication, digital television, and high-speed modems (asymmetric digital subscriber line, x digital subscriber line) are other areas of computing in which error-correcting codes are used.

Instead of transmitting raw digital information, the data are encoded in the form of a "code word" with redundant information using a well-defined set of rules at the source. The code word is then transmitted, and the receiver can decode it to retrieve the desired information while being able to detect and possibly correct any error. A code word is said to be *valid* if it adheres to all of the rules that define the code; otherwise, the code word is said to be *invalid*. The *encoding* process determines the corresponding code word for a given data item, whereas the *decoding* process recovers the original data from the code word. If the code words are formed correctly, errors that are introduced during transmission can be detected during the decoding process at the destination because the code word would be transformed into an invalid code word. This is the basic concept of the *error-detecting codes*. The basic concept of the *error-correcting code* is that the code word is structured such that it is possible to determine the correct code word from the corrupted, or erroneous, code word. A fundamental concept in the characterization of codes is the *Hamming distance*, in which the distance between any two binary words is the number of bit positions in which the two words differ. The Hamming distance gives insight into the requirements of error-detecting codes and error-correcting codes. The *code distance* (C_d) is the minimum Hamming distance between any two valid code words. For a binary code (consisting of digits 0 and 1) to be able to detect up to d bit errors and to correct up to c bit errors, the code distance must be at least $d + 1$ and $2c + 1$, respectively. The same code can correct up to c bit errors and detect an additional d bit errors if and only if $C_d - 2c + d + 1$. For example, a code with a distance of 2 cannot provide any error correction but can detect single-bit errors. Similarly, a code with a distance of 3 can correct single-bit errors or detect a double-bit error. Separability is another fundamental concept in the characterization of codes. A code is *separable* if the code words are formed by appending the check bits to the original information bits. A code is *nonseparable* if the code words are not partitioned directly into information and check bits.

The simplest form of error-detection coding is the single-bit parity check. Single-bit parity codes require

the addition of an extra bit to a binary word such that the resulting code word has either an even number of 1s (even parity) or an odd number of 1s (odd parity). The single-bit parity code (either odd or even) has a distance of 2; therefore, it allows any single-bit error to be detected but not corrected. Perhaps the most common extension of parity is the Hamming error-correcting code, which is designed to detect double errors and correct single errors. The Hamming code allows error correction because the minimum distance between any two *valid* code words is 3. Hamming codes are widely used most to protect memories. The reasons are that it is relatively inexpensive (10% to 40% of redundancy) and very efficient. The Hamming code is formed by partitioning information bits into parity groups. By overlapping the groups of bits, erroneous bits can be detected and corrected. Other forms of error detection coding are: *checksums* and *arithmetic codes* (Siewiorek and Swartz 1998).

Checksums are most applicable when blocks of data are to be transferred from one point to another. These are separable codes and perform error detection by appending extra information to the original data. They are often simple to implement but do not provide good error correction. The checksum is basically the sum of the original data and is appended to the original data. The checksum is then regenerated when the data are received at the destination. The original and the recomputed checksums are compared. An error is signaled if they differ.

Arithmetic codes are very useful when it is desired to check arithmetic operations such as addition, multiplication, and division. The data presented to the arithmetic operation are encoded before the operations are performed. After completing the arithmetic operations, the resulting code words are checked to make sure that they are valid. If the resulting code words are not valid, an error condition is signaled. The primary advantage of the arithmetic codes is that they allow hardware that performs arithmetic operations to be easily checked. The code must be invariant for a set of arithmetic operations. For instance, if an arithmetic code A is invariant for the multiplication, then $A(xy) = A(x)A(y)$, where x and y are operands, and $A(x)$ and $A(y)$ are the arithmetic code words for the operands x and y , respectively. The most common examples of arithmetic codes are the AN codes, residue codes, and the inverse residue codes. The AN code is formed by multiplying each data point, N , by a constant A . The AN codes are invariant to addition and subtractions but not multiplication and division. The correctness of an operation performed using an AN code can be checked by determining whether the result is evenly divisible by A ; otherwise, it is signaled as an error. Selection of A is crucial to the effectiveness and efficiency of the resulting code. Moreover, the magnitude of A determines extra bits required to represent code words and the error-detection capability. For binary codes, A must not be a power of 2. The residue codes are separable arithmetic codes formed by appending the residue r (where r is the residue of N modulo m) of a number N for a given modulus m to that number. Encoding process determines the residue and appends the residue to the original data. Decoding process simply removes the residue. The inverse-residue codes are like residue codes, but rather than appending the residue, the inverse residue $m-r$

(where r is the residue of N modulo m) is calculated and appended.

Two other codes worth mentioning are *m-of-n codes* and *Berger codes*. The *m-of-n codes* are formed by creating code words of size n bits in which there are exactly m number of 1s. Any single-bit error forces the resulting erroneous word to have either $m+1$ or $m-1$ number of 1s. Not only can the error be detected, but also the direction of error (0 to 1 or 1 to 0) can be found. The *m-of-n codes* are conceptually simple, but the encoding, decoding, and detection processes are often difficult to perform. The *Berger codes* are separable codes formed by appending a special set of bits (check bits) to each word of information. The check bits are created based on the number of 0s in the original information. The code word is then formed by appending to the original information the binary representation of the number of 0s found. In general, if we have k information bits then we need $\lceil \log_2(k+1) \rceil$ check bits. The *Berger codes* use the fewest number of check bits of all separable codes.

Time Redundancy

Time redundancy uses additional time to provide fault detection and, sometimes, fault tolerance. It can be used to distinguish between permanent and transient failures. Time redundancy is extremely useful for detecting transient faults but not permanent faults. Simple retries allow for transient fault detection as well as their correction. This method attempts to reduce the amount of extra hardware at the expense of using additional time if that is readily available. The basic concept of time redundancy is to perform the same computation repeated times and compare the results to determine whether a discrepancy exists. If an error is detected, the computations can be performed again to see whether the disagreement remains or disappears. The processor performs the computations one or more times after detecting the first error; if the error condition clears, the processor can assume that the fault was transient. In another form of time redundancy, the same processor performs the same computations multiple times using different coding schemes in each case, with the assumption that the fault may manifest itself in different ways depending on the particular code being used. The main problem with many time-redundancy techniques is ensuring that the system has the same data to manipulate each time it redundantly performs a computation.

Software Redundancy

Unlike hardware, software is not subject to wear-out conditions that occur from aging, stress, or environmental factors. Thus, the only cause of software faults is improper specification or bad design and/or implementation of programs, which results in the inability of the software to meet its designed requirements or specifications under unforeseen circumstances or changes to the computing environment. Although, just like in fault-tolerant hardware, reliable software systems must be able to either eliminate or effectively tolerate and recover from faults. Because modern software systems are so complex, it is nearly impossible to eliminate all of the embedded faults;

therefore, development techniques that protect the entire system from incorrect operation should be used in cases in which program failure would have serious consequences. Like hardware, all software fault-tolerant techniques require redundancy to support the fault-tolerant features. Software redundancy is simply the addition of extra software to provide some fault-tolerance features. The type of redundancy may range from complete replication of software to the addition of small programs to perform validity checks, such as consistency and capability checks. A consistency check is based on prior knowledge of the computation results. If the result is not in a predefined range, then an error has occurred in the computation process. The capability-check technique verifies that a system possesses the capability expected. Apart from the validity checks, there are two important approaches to software fault tolerance: *recovery* and *redundancy*. The recovery is normally achieved through *recovery block* mechanisms, whereas design diversity such as the *N-version programming* is used to provide redundancy.

Error Recovery

Error recovery is a process that brings the system back to an error-free state. It is probably the most important phase of any fault-tolerance technique. There are two approaches to recovery: *backward recovery* and *forward recovery*.

Backward recovery restores the system to a previous safe state, which is referred to as a “recovery point.” The act of establishing the recovery point is called “checkpointing,” which is a process of checking and saving the current system state for recovery. The advantage of backward recovery is that the erroneous state is cleared, and no effort is needed to find the location and cause of the fault. Therefore, this approach is ideal for recovering from unanticipated faults, including design faults. Rollback is one of the backward-recovery mechanisms. Rollback is often used by database systems to return the system state from the unfinished transaction to the previous consistent state by undoing all the steps that have been done since the transaction started. To be able to recover, it is needed

to store the system’s state at the recovery point to a stable storage, such as a hard disk, so recovery needs space. Also, recovery takes time, and the whole process has to be prevented from proceeding by executing a recovery algorithm instead. In a real-time system, because of the tight time constraint to reach a certain state, recovery mechanisms might not be the possible solution to the detected errors.

Forward recovery attempts to continue from an erroneous state by making selective corrections to the system state. This includes making safe the controlled environment, which may be hazardous or damaged because of the failure. Upon the detection of a failure, the system discards the current erroneous state and determines the correct state without any loss of computation. It is system-specific and depends on accurate predictions of the location and cause of the errors (i.e., damage assessment). Exception handling is a forward-recovery mechanism, as there is no rollback to a previous state involved; instead, control is passed to the exception handler so that the recovery procedures can be initiated. There are two basic approaches to backward recovery: one that relies on hardware redundancy (both static and dynamic) and the other on software redundancy. Forward-recovery schemes based on static hardware redundancy mask the failures through redundancy and have very high hardware overhead, whereas forward recovery schemes that are based on dynamic redundancy and checkpointing have lower hardware overhead (Pradhan 2003). The software-redundancy-based approach for forward recovery requires a certain degree of software redundancy as well as hardware redundancy. Error detection is performed by acceptance tests, and the recovery is handled using the recovery block concept, described below.

Recovery Block

The recovery block (RB) mechanism (Randell and Xu 1995) combines the basics of the checkpoint and restart approach with multiple versions of a software component such that a different version is tried after an error is detected (see Figure 9). It detects errors through the

Figure 9: Recovery block

Figure 10: N -version programming

acceptance test after running each alternative. Checkpoints are created before a version executes and are needed to recover the state after a version fails. The recovery blocks use temporal redundancy (i.e., execution of a different version of software after an error has been detected) and software standby sparing. This provides protection against software-induced errors and hardware transient faults. Software is partitioned into several self-contained versions called “recovery blocks.” Each recovery block is composed of a primary version, one or more alternative versions, and an acceptance test. The primary version contains the preferred algorithm for the task. The secondary versions act as standby spares that are designed and coded independently from the primary. The acceptance test is used to test whether the system is in an acceptable state after the first execution of the primary version. The failure of the acceptance test results in the program being restored to the recovery point and the second alternative version is executed. If the second version also fails the acceptance test, then the program is restored to the recovery point and yet another alternative version is executed. If all the alternatives are exhausted, the system fails.

Two issues must be considered when using the recovery-block mechanism (Torres-Pomales 2000):

- *Domino effect*: For two concurrent processes interacting with each other, one process rolling back to its recovery point might cause the other to roll back to its recovery point as well. This procedure could go on until the whole system returns to its original state. This phenomenon is called the “domino effect.” The cause of this phenomenon is that each process is designed to have its own recovery point that does not consider others’ recovery points. Carefully designing a consistent recovery point among all processes that are interacting with each other during execution could avoid this problem.
- *Logging*: Logging is the way used to keep track of modifications since last checkpointing, so the system will be able to roll back to the latest consistent state. Logs need to be saved in persistent storage to survive any crash.

N-Version Programming

The objective of N -version programming (NVP) is to provide fault tolerance through software design diversity. Design diversity assumes that multiple versions of software exist for a particular task and that each of these versions has been designed and coded by people working

independently. The idea is that although each programmer is likely to make some error, all programmers will not make the same error. Hence, the results of running multiple versions of software can be voted upon in the same way that voting is conducted in hardware NMR. The rationale for the use of multiple versions is the expectation that components built differently should fail differently. The concept of NVP was developed by Algirdas Avizienis of UCLA (Avizienis 1985, 1995) to allow certain design flaws in software modules to be tolerated. In NVP, N versions of a software component are developed independently by different individuals/teams with different algorithms, techniques, programming languages, environments, and tools to ensure independent program versions. The N -version programs then run concurrently with the same inputs, and a driver process compares their results. The NVP concept is illustrated in Figure 10.

Another variation of multiversion programming is the N -self-checking programming (NSCP) (Lyu 1995), which is the use of multiple software versions combined with structural variations of RB and NVP. NSCP uses multiple versions of acceptance tests that are independently developed from common requirements. The use of separate acceptance tests for each version is the main difference between RB and NSCP. Like NSCP, other variations of RB also exist, the consensus recovery block (CRB) being one such variation. The CRB approach combines NVP and RB to improve reliability over any of these individual approaches. The CRB uses a decision algorithm similar to NVP as a first layer of decision. If the first layer declares a failure, a second layer using acceptance tests similar to those used in RB approach is used.

Algorithm-Based Fault Tolerance

Algorithm-based fault tolerance (ABFT) can be considered another form of software redundancy. It is based on the use of fault-detection and fault-tolerance techniques specific to an algorithm, which allows for errors in computations to be detected and corrected (Nair, Abraham, and Banerjee 1996). The ABFT techniques have been proposed for various signal-processing computations, such as matrix operations, fast Fourier transforms, factorization, etc. (Huang and Abraham 1984). For example, in a matrix operation, each matrix can be augmented with a row or column checksum. If the checksum is erroneous, the error will be detected, the location of the error can be identified, and the erroneous entry can be corrected. This can be illustrated with the following example.

Example: Suppose we want to multiply two 2×2 matrices A and B to get a 2×2 matrix C as given below:

$$A = \begin{pmatrix} 8 & 3 \\ 5 & 4 \end{pmatrix}, B = \begin{pmatrix} 2 & 4 \\ 6 & 7 \end{pmatrix}, C = AB = \begin{pmatrix} 34 & 53 \\ 34 & 48 \end{pmatrix}.$$

Instead of multiplying A and B to get C , we multiply A_{res} (the row checksum matrix of A) and B_{ccs} (the column checksum matrix of B) to get C_{cs} as shown below. C_{cs} happens to be the checksum matrix of C .

$$A_{res} = \begin{pmatrix} 8 & 3 \\ 5 & 4 \\ 13 & 7 \end{pmatrix}, B_{ccs} = \begin{pmatrix} 2 & 4 & 6 \\ 6 & 7 & 13 \end{pmatrix}, C_{cs} = \begin{pmatrix} 34 & 53 & 87 \\ 34 & 48 & 82 \\ 68 & 101 & 169 \end{pmatrix}.$$

Now suppose that the (2,2) entry of C_{cs} is incorrect (say, 32 instead of 48). Not only can any single error be detected, the location of the error also be identified by taking the intersection of the row and column in which the checksums are erroneous. In our case, both row 2 checksum and column 2 checksum will signal an error, pointing to the error location (2,2), since $34 + 32 \neq 82$ and $53 + 32 \neq 101$. The erroneous entry can also be corrected with the value that will give the correct checksum in row 2 and column 2.

Self-Checking Design

As digital systems get more and more complex, it is becoming highly desirable to have systems that have self-checking capability. A circuit is called "self-checking" if it has the ability to automatically detect the existence of a fault without the need for externally applied test stimuli (Lala 1985). Self-checking design uses the error-detecting codes to encode the output. The basic idea behind this design is that during fault-free operation, the output of such a circuit is always a code word, and hence, an invalid code word at the output will signal the existence of a fault. Two concepts that define self-checking design need to be discussed. A circuit is said to be *fault-secure* for a given set of faults, if for any fault in the set, the circuit never produces an incorrect code word for any valid input code word. In other words, a circuit is fault-secure if the fault either has no effect on the output, or the output is affected such that it becomes an invalid code word. A circuit is said to be *self-testing*, if there exists at least one valid input code word that will produce an invalid output code word when a single fault is present. A circuit is *totally self-checking* if it is both fault-secure and self-testing. A totally self-checking circuit will always produce either the correct code word at the output or an invalid code word, and there will be at least one valid input code word that will produce an invalid output code word when any single fault is present. If the circuit is self-testing for a set N of normal inputs and a set F of faults, and is fault-secure for a subset of inputs and a subset of faults, then this circuit is called *partially self-checking*. A circuit is called *fail-safe* if the output is either correct or belongs to the set of safe outputs. The traffic light with a fail-safe output as flashing red on all sides is a good example of a fail-safe circuit. An application of the self-checking technique

Figure 11: Basic structure of a totally self-checking circuit

is the programmable logic array, which is a common structure in very-large-scale integration (VLSI) designs. The basic structure of a totally self-checking circuit is shown in Figure 11.

In this figure, the function of a checker is to determine whether the output of the functional circuit is a valid code word. In addition, the checker must indicate if any fault has occurred in the checker itself. To accomplish both tasks, the output of the checker is encoded to produce an error signal. The checker has two bits of output. The outputs are complementary if the input to the checker is a valid code word and the checker is fault-free; otherwise, they are noncomplementary. The checker must possess *code disjoint* property, which means when the checker is fault-free, the valid code words on the checker's input lines must be mapped into valid error codes (the checker's outputs are complementary) on a checker's output lines. Likewise, invalid code words on a checker's input lines must be mapped into invalid error code words (the checker's outputs are noncomplementary) on the checker's output. There is no simple, systematic method to use in the design of totally self-checking checkers. The most common totally self-checking checker is the two-rail checker, as shown in Figure 12.

The two-rail checker is used to compare two words that should normally be complementary. It will produce complementary error signals e_1 and e_2 if the inputs are complementary; otherwise, the error signals will be non-complementary. The two-rail checker satisfies the fault-secure property for the following reason. Both e_1 and e_2 are generated by two physically separate circuits. Because the error signals are defined as complementary, any fault that affects one of the two signals will cause e_1 and e_2 to be noncomplementary. A fault either does not impact error signals or it forces error signals to no longer remain complementary. Faults on primary input to the checker simply appear to the checker as invalid code words and result in noncomplementary outputs. Similarly, it can be shown that the two-rail checker also satisfies the self-testing property, making it a totally self-checking checker. Totally

$$e_1 = e_2' \text{ if and only if } x_i = y_i' \text{ for all } i.$$

Figure 12: A two-rail checker

Figure 13: The general structure of a totally self-checking checker for the Berger code

self-checking checkers can be designed for any application. Figure 13 shows the general structure of a totally self-checking checker for the Berger code.

Survey of Fault-Tolerant Systems

Since the early 1950s, fault-tolerance techniques have been used to achieve highly reliable hardware operation. High reliability in computer design was first achieved through fault-avoidance techniques; these involved computer design that used high-quality, thoroughly tested components. Simple redundancy techniques were used to achieve limited fault tolerance. Examples of the first digital computers to use error-detection and fault-tolerance techniques to overcome the low reliability of their basic components are: the Bell Relay Computer (BRC), which had two CPUs; the IBM 650 and UNIVAC, which incorporated parity to check results of data transfer; and EDVAC, which was the first computer to have two arithmetic logic units (ALUs). With the advent of transistors, the emphasis of fault-tolerant computing decreased temporarily. It was not until computers began performing more critical tasks (for the U.S space program and in military applications) that fault tolerance again surfaced as a critical issue. Today, the increasing public dependence on automated services combined with the lower cost and increased performance of semiconductor technology has contributed to a renewed interest in fault-tolerant computing.

The major thrusts behind the development of fault-tolerant computing have been high reliability, high availability, reduced life-cycle cost, and long-life applications. Four major application areas of fault-tolerant systems are (ordered by increasingly stringent reliability requirements): general-purpose commercial applications, high-availability applications, long-life applications, and critical-computation applications. DEC VAX-11/780, IBM S/360-S/370-4300 family, Univac 1100/60 are some examples of general-purpose commercial applications. Banking and other time-shared systems are good examples of high-availability applications. Tandem (Dimmer 1985), Stratus (Webber and Beirne 1991), Pluribus (Katsuki et al. 1978), Electronic Switching System (ESS) (Toy 1978), and Intel 432 are some examples of high-availability applications. Users of these systems want to have a high probability of receiving service when it is requested. The Tandem NonStop transaction processing system is a good example of a system designed for high availability. The Intel 432 processor system is an example developed to support high availability in many general-purpose processing applications. The most common examples of long-life applications are unmanned space flight and satellites. The self-testing and repairing (STAR) computer (Avizienis

et al. 1971), Pioneer, Voyager, Galileo, the fault-tolerant spaceborne computer (FTSC) (Burchby, Kern, and Sturm 1976), and the fault-tolerant building block computer (FTBBC) are some examples of long-life applications that have a system operating life over 5 years. These systems are highly redundant, with enough spares to survive the mission with required computational power. Typical long-life applications are to have 0.95 probability of being operational at the end of a 10-year period. Examples of critical-computation applications include aircraft flight-control systems, military systems, and certain types of industrial controllers. Examples of some critical-computation applications are the space shuttle computer (Sklaroff 1976), C.vmp (Siewiorek et al. 1978), the software-implemented fault-tolerance (SIFT) computer (Wensly et al. 1978), the fault-tolerant multiprocessor (FTMP) (Hopkins, Smith, and Lala 1978), aircraft-control systems, military systems, and industrial control systems. The design goal is the failure probability of less than 10^{-9} for a 10-hr mission. A typical requirement for a critical computation application is to have a reliability of 0.9999999 at the end of a 3-hr period. SIFT and FTMP are avionic computers designed to control dynamically unstable aircraft. In a critical computation application, computations must not only be correct, but recovery time from faults must be minimized. Specially designed hardware is implemented with concurrent error detection so that incorrect data never leave the faulty module.

In the remainder of this section, we will briefly review the main features of some of these fault-tolerant systems. Discussions on other fault-tolerant systems can be found in Pradhan (2003), Siewiorek and Swartz (1998), and Neil (2005). The features of a fault-tolerant storage device called the "redundant array of independent disks" (RAID), which uses multiple hard drives for sharing or replicating data among the drives to achieve fault tolerance, are also described as a related topic. In recent years, computer networks and the Internet have played an important role in modern society. Numerous network-based applications and services have made the availability and reliability of networks crucial. As a result, fault-tolerance ability is strongly needed by networks. This section will conclude with a discussion on fault tolerance in the context of networking and the Internet.

Tandem

Tandem computers (Dimmer 1985) were the early fault-tolerant computers built for high-availability applications to cope with the rising transaction-processing needs in banks, automatic teller machines (ATMs), stock exchanges, etc. The Tandem 16 NonStop System, built in 1976, supported up to sixteen processors in a multicomputer

To guarantee that the backup process has the information to perform a required function, the primary process sends checkpoint messages to the backup process. The checkpoint messages specify the state of the primary process at certain critical points during the computation. If the primary process fails, the backup process is started using the most recent checkpoint information. Tandem systems use retry extensively to access I/O devices. For the past two decades Tandem systems have evolved considerably, and have been under the ownership of Compaq since 1997.

Space Shuttle Computer

In 1976, the space shuttle computer was probably the most difficult and complex machine ever built for critical-computation applications. The space shuttle computer system is responsible for providing flight-critical functions during the ascent, reentry, and descent of the spacecraft. The computer system consists of five identical IBM 32-bit general-purpose computers, each capable of performing critical and noncritical functions. In 1990, the original computers were replaced with IBM's upgraded model AP-101S, which has about 2.5 times the memory capacity (about 1 Mb) and three times the processor speed (about 1.2 million instructions per second). Each general-purpose computer consists of a CPU and an I/O processor. Four of these computers run a specialized software called the "primary avionics software set" (PASS) and are used as a redundant set during critical mission phases. The fifth computer, which acts as a backup to the primary system, runs a completely independent piece of software called the "backup flight software" (BFS) and performs noncritical tasks such as communications control and display processing. It sits in a "listen" mode, monitoring what is going on, unless it is commanded by the crew to take over. The four primary computers form an NMR arrangement, receive the same input, and perform the same computations. Each of these four computers listens to the output of the remaining three and compares those signals with its own. If one computer fails, the three functioning computers "vote" it out of the system. If a second of the three remaining computers fails, the system converts to a duplex system that can survive an additional computer failure by using comparison and self-tests to isolate the failure. The PASS was written by IBM, and the BFS was written by Rockwell International to minimize the probability of a common software error (Sklaroff 1976).

STAR

The self-testing and repairing (STAR) computer (Avizienis et al. 1971) was developed by the Jet Propulsion Laboratory (JPL), under the supervision of Algirdas Avizienis, for a 10-year mission to outer space. Although the design is over 30 years old, many of the techniques in this system are applicable today. The STAR computer was designed to handle guidance, control, and data acquisition on unmanned missions. It was desired to achieve a probability of 0.95 that the STAR computer would be completely operational at the end of 10 years. The designers of the STAR computer selected the dynamic redundancy method for achieving fault tolerance. The STAR computer uses cold standby sparing to achieve fault tolerance.

Cold standby sparing incorporates active units with two spares. Error detection and reconfiguration are done by means of a special hardwired TMR test and repair processor (TARP) computer. The TARP computer uses triplication with voting and two spares to achieve fault masking and recovery. Each functional unit (control processor, logic processor, main arithmetic processor, and memory unit) performs its own fault detection. The TARP provides error checking on information transmitted over buses and reconfigures the system in the event of a unit failure. Error-detecting codes are used on all data and instruction words. The STAR system uses two primary types of error-detecting codes: the inverse residue code and the 2-of-4 code. However, the logic processor and the read/write memory use duplication and comparison for error detection. This scheme is defined as either shadow memory or mirrored memory. The TARP unit also operates as a watchdog timer. If a unit fails to send its periodic signal, the TARP computer considers the signal as a faulty unit and replaces it with a spare. The design of the STAR computer has been successful. It achieved a reliability of greater than 0.95 after 10 years of operation. A significant result of the STAR computer design was that it paved the way for future research in fault-tolerant computing. Many of the approaches tried and proven in the STAR design remain valid today.

Stratus

Founded in 1980, Stratus Computers competed mostly with Tandem Computers in transaction-processing applications. The Stratus systems are continuously checking between duplex components for detection of errors. The Stratus self-checking, duplicate-and-match architecture (see Figure 15) is composed of replicated power and backplane buses (StrataBus) into which a variety of boards are inserted. A Stratus computer system consists of up to thirty-two modules connected through a Stratus intermediate bus (StrataLink). Using StrataLink, the Stratus operating system provides a global system view of all devices in the system. The StrataLink consists of two independent coaxial links, each link running at 1.4 Mbps. The two processor boards (each containing a pair of multiprocessors) are self-checking modules used in a pair-and-spares configuration, each operating independently. Each half (A half or B half) of each board receives inputs from its own bus (bus A or bus B). The boards compare their two halves. Upon disagreement, a board signals malfunction and removes itself from service. The operating system executes diagnostics on the failed board to determine whether the error was due to a transient or a permanent fault. The Stratus hardware approach does not require on-line recovery from faults; the spare component continues processing until its faulty counterpart can be replaced. The fault-tolerant architecture isolates users from almost all hardware failures. System crashes are minimized with the use of software fault-recovery procedures.

RAID

RAID (redundant array of independent disks) is a family of techniques for managing multiple disks to provide desirable cost, data availability, and performance

Figure 15: Stratus pair-and-spare architecture

characteristics to host environments. A RAID appears as a single drive. In principle, the same data are stored in many places on multiple disks to protect the data in the event of disk failure. RAID uses the technique of disk striping, which involves partitioning each drive's storage space into stripes that can be as small as one sector (a few bytes) or as large as several megabytes. The stripes of all the disks are interleaved in a round-robin fashion so that different stripes of the same file can reside in different physical drives. A disk controller in RAID manages the array of disk drives in such a way that data are protected. By mapping segments or by generating parity bits and storing them on the array, data can be regenerated if a disk drive fails. The manner in which data are placed onto the array provides for increased performance in different data structure environments.

There are many levels of RAID (AC&NC 2005; Chen et al. 1994), which are summarized below:

- **RAID-0:** This is the most basic level of RAID, which comes with striping but no redundancy. It is not a true fault-tolerant configuration, but it offers the best performance.
- **RAID-1:** This type is also known as *disk mirroring* and consists of at least two drives that duplicate the storage of data without any striping (see Figure 16). Read performance is improved, since either disk can be read at the same time. Write performance is the same as for single disk storage. RAID-1 provides the best performance and the best fault tolerance in a multi-user system, but it is most costly in terms of required disk overhead.
- **RAID-2:** This type uses striping across disks and handles the failed components with much less cost than mirroring by using error-correcting codes (ECC). This

Figure 16: RAID-1 mirroring

type uses striping across disks, with some disks storing ECC information. It uses the storage more efficiently than mirroring.

- **RAID-3:** This type introduces a more efficient way of storing data while still providing error correction. It uses striping, uses byte interleaved parity, stores parity information on a separate drive, and performs error checking. Data recovery is accomplished by calculating the exclusive OR (XOR) of the information recorded on the other drives. Since an I/O operation addresses all drives at the same time, RAID-3 cannot overlap I/O. For this reason, RAID-3 is best for single-user systems with long record applications.
- **RAID-4:** This type uses large stripes, which means one can read records from any single drive. This allows one to take advantage of overlapped I/O for read operations. Since all write operations have to update the parity drive, no I/O overlapping is possible.
- **RAID-5:** This type eliminates the parity disk bottleneck present in RAID-4 by distributing the parity uniformly over all the disks (rotating parity). Thus, all read and write operations can be overlapped. RAID-5 stores parity information but not redundant data (parity information is used to reconstruct data). RAID-5 requires at least three and usually five disks for the array. It is best for multi-user systems in which performance is not critical or which do few write operations.
- **RAID-6:** This type is similar to RAID-5 but includes a second parity scheme that is distributed across different drives, and thus offers extremely high fault- and drive-failure tolerance. The extra cost of additional space for parity drives has made RAID-6 rather unpopular.
- **RAID-7:** This type includes a real-time embedded operating system as a controller, caching via a high-speed bus, and other characteristics of a stand-alone computer.
- **RAID-10 (or RAID-1+0):** This hybrid configuration combines the best features of striping (RAID-0) and mirroring (RAID-1) to offer higher performance than RAID-1 but at much higher cost. This configuration comes in two forms: (1) RAID-0+1, in which data are organized as stripes across multiple disks, and then the striped disk sets are mirrored; and (2) RAID-1+0, in which the data are mirrored and the mirrors are striped.
- **RAID-50 (or RAID-5+0):** This type consists of a series of RAID-5 groups and striped in RAID-0 fashion to

improve RAID-5 performance without reducing data protection.

- *RAID-53 (or RAID-5+3)*: This type uses striping (in RAID-0 style) for RAID-3's virtual disk blocks. This offers higher performance than RAID-3 but at much higher cost.

In summary, most RAID systems allow hot replacement of disks, which means that disks can be replaced while the system is running. When a disk is replaced, the parity information is used to rebuild the data on the disk. Rebuilding occurs while the operating system continues handling other operations, so there is some loss of performance during the rebuilding operation.

Fault-Tolerant Networking

The Internet has revolutionized the way people work and communicate. It is, therefore, important to ensure that the Internet continues to function reliably in the event of attacks and errors. In early packet switched network designs, the focus was on handling physical failures, such as link or node failure. More recently, the focus has shifted toward protecting routing protocols against more complex faults to ensure uninterrupted packet delivery. Many network vendors have already integrated fault-tolerance techniques into their systems or equipment.

A fundamental component of the Internet functionality is routing and therefore, it is critical to ensure its correctness and reliability. The abnormal routing behavior can happen because of compromised routers or by human error. Routing can be interrupted because of physical failures, operational faults, error in routing protocol design and/or implementation, compromised routers, and human error. Network resource exhaustion, which can be caused by software viruses, may also affect routing operation due to the in-line signaling nature of Internet routing protocols. Furthermore, malicious attacks can be directly aimed at routers, causing router overload and disrupting packet delivery. There are various defense schemes available against these attacks. Pei, Massey, and Zhang (2004) described a framework that divides defenses into different classes: cryptographic schemes, statistical anomaly detection, protocol syntax checking, and protocol semantic checking. Cryptographic mechanisms primarily aim at locking out external attackers. Anomaly detection, syntax, and semantics checking primarily provide essential detection mechanisms that notice when prevention has failed and also when unexpected faults occur. Secure neighbor-to-neighbor communication to prevent an outside entity from tampering with the messages exchanged between router, authentication to validate the identity of a legitimate router, and authorization to restrict the actions of a legitimate router are among the cryptographic protection schemes. These are all achieved through public-key cryptography. Statistical anomaly detection is based on statistical profiles to flag unexpected behavior. The abnormal routing behavior can happen because of compromised routers or by human error. Protocol syntax checking can be an effective means for detecting hardware faults and implementation error such as illegitimate message sequences. Protocol semantics checking can improve

protocol behavior by monitoring the routing update messages among the routers.

The Internet was designed for fast packet delivery rather than reliability. The transmission in Internet is not fault-tolerant, but reliable delivery services are critical for certain applications, such as file transfer, database services, transaction processing, etc., which require every packet to be delivered. Though transport control protocol (TCP) provides reliable services, it depends on Internet protocol (IP) to deliver packets. IP sends and receives packets to and from IP addresses, but IP does not protect against data loss, data damage, packet out of order, or data duplication. IP is inherently unreliable, so TCP has to be responsible for verifying the correct delivery of data and requesting retransmissions. Several alternatives have been proposed for making TCP fault-tolerant, some of which are discussed below.

FT-TCP (fault-tolerant TCP) (Alvisi et al. 2001) allows the TCP connections to remain open until the faulty server recovers or is failed over to a backup, masking the failure from the client. To realize this, a wrapper software is used to surround the TCP layer and intercept all communication. Two wraps on both the IP and application sides communicate with a logger to record the state and cooperate to maintain or restore the TCP connection. FT-TCP does not need the modification of TCP protocol, nor does it affect the software running on a client, but the logger becomes a single point of failure. ST-TCP (server fault-tolerant TCP) (Marwah, Mishra, and Fetzer 2003) adopts the primary-backup approach, which uses an active backup server to tolerate TCP server failure by taking over the TCP connection. The backup server monitors the state of TCP connection between the client and the primary server and stores it as a replica of the primary application. No change or wrapper is required on the client machine, and the clients can connect to a ST-TCP server in the same way they connect to a standard TCP server. ST-TCP requires minor changes to the standard TCP server and can only tolerate single failure.

HARTs (high availability with redundant TCP stacks) (Shao et al. 2003) uses two or more servers as the primary servers to maintain redundant TCP connection stacks and to improve availability of TCP connections. Therefore, any failure in one of the server nodes does not interrupt the TCP connections. HARTs makes the redundant TCP connections as single networking, but multiple servers must be synchronized.

M-TCP (migratory TCP) (Sultan et al. 2002) also uses multiple servers. A client establishes a TCP connection with one of the servers, but the connection can migrate to another server depending on the migration policy used. The original server transfers the state of this connection to the new server, which starts a new TCP connection and restores the state, and then sends a message to the client to continue its operation. The migration is transparent to the client application. It may be triggered by conditions such as a server crash, network congestion, or degradation.

CONCLUSION

Fault-tolerant computing already has been playing a major role in communications, transportation, e-commerce,

space, and many other areas that impact our lives. Computer architecture is changing because of development in the computer hardware and software design, which presents new challenges to the fault-tolerant industry. Many of its next advances are seen in new state-of-the-art systems such as massively parallel scalable computing, promising new unconventional architectures such as system-on-chip, processor-in-memory, or reconfigurable computing, mobile computing, and the other exciting new things that lie around the corner. Lately, there has been increasing focus on making applications fault-tolerant. Emerging multicast applications such as videoconferencing, distributed network games, telemedicine, distance learning, etc., need fault tolerance to ensure high levels of quality. Therefore, the interest in fault-tolerant systems, fault-tolerant computing, and fault-tolerant applications will keep increasing.

GLOSSARY

ABFT: Algorithm-based fault tolerance.

Availability, $A(t)$: The probability that a system is operating correctly and is available to perform its functions at the instant of time t .

CRB: Consensus recovery block.

Dependability: The quality of service provided by a particular system.

Error: The occurrence of an incorrect value in some unit of information within a system.

Failure: A deviation in the expected performance of a system.

Fault: A physical defect, imperfection, or flaw that occurs in hardware or software.

Fault avoidance: A technique that attempts to prevent hardware failures and software errors from occurring in a system.

Fault Tolerance: The ability to continue the correct performance of functions in the presence of faults.

Fault-Tolerant Computing: The process of performing calculations, such as those performed by a computer, in a fault-tolerant manner.

Maintainability, $M(t)$: The probability that the failed system can be restored to operation within time t .

MTBF: Mean time between failures.

MTTF: Mean time to failure.

MTTR: Mean time to repair.

NMR: N-modular redundancy.

NSCP: N-self-checking programming.

NVP: N-version programming.

RAID: Redundant array of independent disks.

RB: Recovery block.

Reliability, $R(t)$: The conditional probability that a system has functioned correctly throughout an interval of time, $[0, t]$, given that the system was performing correctly at time 0.

TMR: Triple modular redundancy.

In mechanics we used only one clock. But this was not very convenient, because we had to take all measurements in the vicinity of this one clock. Looking at the clock from a distance, ... we have always to remember that what we see now really happened earlier, just as we receive light from the sun eight minutes after it was emitted. We should have to make corrections, according to our distance from the clock, in all our time readings.

—Einstein and Infeld (1938)

Now what does that mean? If we look at the situation carefully we see that events that occur at two separated places at the same time, as seen by [an observer] in [a coordinate system], do *not* happen at the same time as viewed by [another observer] in [another coordinate system]. ... This circumstance is called “failure of simultaneity at a distance,”...

—Feynman, Leighton, and Sands (1963)

INTRODUCTION

Let G be a connected undirected graph with n nodes and m edges. Each node in G stands for a sequential processing element and each edge represents a bidirectional communication channel that allows for the point-to-point exchange of messages between its end nodes. G is then representative of a multitude of distributed-memory systems, such as computer networks and, more abstractly, systems of multiple agents that do not share memory. In this chapter, we understand a distributed algorithm to be any algorithm for execution by the nodes of G as concurrent sequential threads that communicate with one another by passing messages over the edges of G . We let nodes be numbered $1, \dots, n$.

The field of distributed algorithms is an outgrowth of the research on concurrent programming that some decades

ago was an essential part of the research on operating systems. The field evolved to encompass both the message-passing computations that are our subject matter in this chapter and computations on shared memory. Through the years, key representative problems have been identified, and a core collection of fundamental techniques has been put together for use in the design and analysis of the algorithms. In a space-constrained chapter such as this one, it is unavoidable that some topics be left out (such as the entire sub field of shared-memory computations) while others are only skimmed over (such as computations in the presence of faults, which we cover later only briefly). However, we are at present fortunate to have several texts on distributed algorithms available for in-depth study. Of these, we single out the books by Barbosa (1996), Lynch (1996), Peleg (2000), Tel (2000), and Attiya and Welch (2004). Each favors a different approach to the subject and has its particular choice of topics. Combined, they offer a comprehensive body of knowledge on the field.

Most of the research on distributed algorithms has had a strongly theoretical flavor and has striven for the rigorous establishment of correctness—and performance-related properties. As the reader will notice throughout the chapter, often the approach has been to concentrate efforts on a few paradigmatic problems whose definitions aim at capturing the practical issues pertaining to real-world problems. For readers of a handbook such as this, it is important to realize that this approach has been very successful and that many practical solutions exist that implement what has been discovered. Two important examples are the applications of leader-election algorithms, particularly within the asynchronous transfer mode (ATM) layers that lie at the Internet's backbone (Huang and McKinley 2000), and the use of algorithms to discover minimum-weight spanning trees on overlay networks for end-system multicast (Chu et al. 2002). Even conceptual problems whose treatment is fraught with difficulties, such as reaching agreement in faulty environments, have influenced real-world decisions: the four-way handshake that implements the closing of TCP connections (Kurose and Ross 2005),

for example, is an attempt to handle the difficulties of such an agreement.

The two quotations that open this chapter are meant to stress what we deem to be the most fundamental issue underlying the study of distributed algorithms—that is, the issue of how to represent time, how to account for its passage, and how to refer to global entities without breaching any causality principles. We deal with this issue in the section on “Models of Computation,” albeit still somewhat superficially, with the introduction of the so-called synchronous and asynchronous models of computation that we use throughout the chapter. The section also contains representative distributed algorithms for each model. The asynchronous algorithms, in particular, are expanded and generalized in the section on “The Quintessential Asynchronous Algorithm” to yield a template for any asynchronous algorithm. We then continue in the section on “An Asynchronous Building Block” with the introduction of an important building block to be used in the construction of asynchronous algorithms. This building block is intended for the asynchronous establishment on G of a rooted tree having certain desired properties.

In the section on “Events and Global States,” we return to time-related modeling issues and expand on the asynchronous model by introducing details that eventually lead to the notion of a consistent global state of an asynchronous computation. This is followed by a section on “Other Asynchronous Building Blocks,” in which two additional building blocks for the construction of asynchronous algorithms are discussed, namely the election of a leader and the distributed recording of a global state. Provisioned now with three important building blocks, we move in the next section to the description of an asynchronous algorithm that can be built out of some of them.

The issue of how to assess the computational complexity of a distributed algorithm is treated in the section on “Computational Complexity,” in which we discuss both time- and communication-related measures. With these in hand, we are equipped not only to analyze the worst-case performance of the algorithms discussed up to that section, but mainly we can then return to the interplay between synchronism and asynchronism and describe how to safely translate a synchronous algorithm into an asynchronous one while being able to assess the unavoidable change in computational complexity. We do this in the next section, in which we discuss the so-called synchronizers.

The section titled “Additional Topics” is devoted to brief discussions of further topics of interest within the field both from a theoretical perspective (viz. lower bounds and impossibility results, computing on anonymous systems, topological awareness, self-stabilization, consensus problems, correctness proofs, and the emergence of an all-encompassing theory of distributed computing) and from an applications-related one (resource sharing and the design of asynchronous algorithms for wireless networks and for large unstructured networks of generally unknown topologies—the so-called complex networks). To finalize, we give conclusions and closing remarks.

MODELS OF COMPUTATION

We give each model of distributed computation by specifying how time elapses at each node of G , how the elapsing of

time at one node relates to what happens at another node, and how the passing of messages relates to time. For most of the chapter we assume that nodes and edges never fail.

The Synchronous Model

The synchronous model of distributed computation is characterized by the existence of a single clock that makes all nodes work in lockstep at the occurrence of its pulses, numbered by the integer $s \geq 0$. The model also assumes that the local computation occurring at each node for each pulse takes no time, and also that messages sent between neighbors in G as part of the local computation for pulse s are delivered before the occurrence of pulse $s + 1$. The assumptions of the synchronous model are unrealistic, but allow for great simplifications in the design of distributed algorithms, as we exemplify next.

Example: breadth-first numbering This problem asks that each node i in G be labeled with the integer l_i such that the number of edges on the shortest path (i.e., the distance) from node i to node 1 is l_i . A synchronous algorithm to do this is initiated by node 1, which at pulse $s = 0$ lets $l_1 = 0$ and sends a message to all its neighbors. For $s > 0$, any node i receiving a message for the first time lets $l_i = s$ and also sends a message to all its neighbors. Clearly, the problem can be solved within $\text{diam}(G) + 1$ pulses, where $\text{diam}(G)$ is the diameter (greatest distance between two nodes) of G . The number of messages used is $\sum_i d_i = 2m$, where d_i is the degree of node i .

Example: leader election in a complete graph When node i has an identification id_i that is distinct from all other nodes' and all identifications are totally ordered by $<$, this problem asks that all nodes in G determine the node k for which $id_k = \min_i id_i$. A nontrivial synchronous algorithm to do this on a complete graph is the following (Afek and Gafni 1991). Initially all nodes are candidates. At each even pulse, a node i that remains a candidate sends id_i to a new group of neighbors. At each odd pulse, every node compares all the identifications sent to it in the previous pulse to the least identification it has ever seen and, correspondingly, sends out at most one positive reply (to the owner of the new least identification, if any). A node remains a candidate if it receives positive replies to all identifications it sent out. If at pulse $s = 2z$, $z = 0, 1, \dots$, the group of neighbors to which a candidate's identification is sent has size 2^z , then clearly the number of pulses required to elect a leader is $O(\log n)$. As for the number of messages, notice that the number of candidates remaining at pulse $s = 2z$ for $z > 0$ is the number of nodes that were sent 2^{z-1} positive replies at pulse $s - 1$ —that is, at most $n/2^{z-1}$. The overall number of messages includes the initial n identifications, the $(n/2^{z-1})2^z$ identifications sent for each $z > 0$, and finally the $O(n \log n)$ positive replies. These add up to $O(n \log n)$ messages.

Both examples take explicit advantage of the assumptions of the synchronous model. In the case of breadth-first numbering, this is revealed in the one-to-one correspondence between a node's distance to node 1 and the earliest pulse at which it can be reached by a message initially propagated by node 1. In the case of leader election

when G is a complete graph, it is revealed in a subtler manner by the tacit information that, in the synchronous model, necessarily accompanies the absence of a message. The algorithm in the example exploits this by letting each node group all identifications sent to it before deciding whether to send out a positive reply, and also by dispensing with the need for negative replies.

The Asynchronous Model

In the asynchronous model, each node has its own local, independent clock, and computes, possibly sending out messages to its neighbors, upon the receipt of each message. Message delivery, even though guaranteed to occur, is in no way correlated to either the clock of the sender or of the receiver. The reactive response to an arriving message is always atomic—that is, it is never interrupted by the arrival of new messages, which are then queued up for future treatment. These assumptions, clearly, call for the existence of at least one initiator, that is, at least one node that performs some initial local computation, and sends out messages, without the need for an arriving message to respond to. We henceforth consider asynchronous algorithms nearly exclusively. They are in general more complex than synchronous algorithms; we start with very simple examples (Segall 1983).

Example: flooding Let I be a piece of information to be disseminated through the nodes of G from a single initiator, say node 1. In the absence of any further structure on G , one solution is to flood the graph: node 1 sends I to

all its neighbors; all other nodes, upon receiving I for the first time, do the same. Clearly, this requires $2m$ copies of I to be sent out.

Example: flooding with feedback Suppose that, in addition to disseminating I as in the previous example, we also want node 1 to be informed that all other nodes have already been reached by the dissemination when this happens. Let p_i be a variable local to node i . We use flooding with feedback: node 1 sends I to all its neighbors; node $i \neq 1$, upon receiving I for the first time, say from node j , lets $p_i = j$ and sends I on to all its neighbors but j ; node j is sent I back only when node i has received I from all its neighbors. The number of copies of I required is still $2m$, but now a simple inductive argument on the spanning tree rooted at node 1 that the p_i variables establish on G shows that node 1, upon having received I from all its neighbors, is certain that the dissemination has finished (Figure 1(a)).

The first example is valid for any number of concurrent initiators. The second one, with its inherent ability to anchor the entire asynchronous computation, via the rooted tree, at the single initiator, gives rise to both a generic template for gracefully terminating asynchronous algorithms (cf. the section on “The Quintessential Asynchronous Algorithm”) and also a fundamental building block for the development of asynchronous algorithms (cf. the section on “An Asynchronous Building Block”).

THE QUINTESSENTIAL ASYNCHRONOUS ALGORITHM

Any asynchronous algorithm with one single initiator can be cast into the template we give in this section. In the case of algorithms that rely on the flexibility of multiple concurrent initiators, the same property continues to be ultimately valid in its essence, since conceptually we can always add a new node to G , connect this node to the desired initiators, and then let it be the sole initiator instead. Our template is based on the elegant method laid down by Dijkstra and Scholten (1980) for detecting the termination of asynchronous computations that have one single initiator.

We start with a generic template for an asynchronous computation with one single initiator that does not require the initiator to be informed of termination. Such a template requires that the initial action to be performed by the initiator be specified, and also that for all nodes (including the initiator) a specification be given as to how to respond to the reception of each possible message type during the computation. As a shorthand, we refer to such messages generically as msg , always bearing in mind that msg may stand for several different message types, each requiring a different treatment when received.

The generic template we seek in this section is an augmentation of the simple template we just outlined that aims at ensuring that the initiator be informed of termination when it occurs. It uses the same p_i variables of the flooding with feedback algorithm for basically the same purpose. In addition, it is based on the premise that every msg message is explicitly acknowledged—that is, for every msg that node i sends node j there has to correspond an

Figure 1 In the G of part a, directed edges are used to indicate a tree rooted at node 1 that may result from flooding the graph with feedback. The events of a possible execution leading to this tree are shown as filled circles in part b, where dotted lines indicate the nodes' local time axes (time progresses from left to right) and arrows depict messages. The B relation that corresponds to this execution is the edge set of the precedence graph of part c. One of the execution's global states is shown in part d, where the dashed line is used to indicate the corresponding partition of the event set. The only messages to be sent in the future of this global state are the copies of I that traverse tree edges root-ward to implement feedback.

acknowledgment message sent by node j to node i . We let such a message be generically denoted by *ack*. Deciding when to send each *ack* is the crux of the underlying method. For node i , a counter c_i , initially set to 0, is used to keep track of how many *ack* messages node i still expects to receive.

The following three actions specify the template asynchronous algorithm. As before, we let node 1 be the algorithm's sole initiator.

1. *Spontaneous initiation at node 1*—Perform some local computation, possibly sending out *msg* messages and incrementing c_1 by the number of messages sent.
2. *Upon the reception of msg from node j at node i* —Perform some local computation, possibly sending out *msg* messages and incrementing c_i by the number of messages sent. Then do one of the following:
 - (a) If $c_i = 0$ held when *msg* was received and $c_i > 0$ holds now, then let $p_i = j$;
 - (b) Otherwise, send *ack* to node j .
3. *Upon the reception of ack at node i* —Decrement c_i and check whether $c_i = 0$. In the affirmative case, conclude that termination has occurred if $i = 1$, or send *ack* to p_i if $i > 1$.

Any asynchronous computation conforming to this template spreads out from node 1 and, if termination ever occurs, eventually contracts back onto it. In the meantime, the computation remains anchored at node 1 through the tree rooted at node 1 that the variables p_i induce if $c_i > 0$. This tree grows with the incorporation of node $i > 1$ into it when in action 2(a) node i lets $p_i = j$; likewise, it contracts by shedding node $i > 1$ when in action 3 node i sends *ack* to p_i . As the computation progresses, such a node may enter and leave the tree several times, each time through a possibly different path from node 1 to it in G . For computations that do terminate, eventually the tree stops growing and then the same inductive argument used to demonstrate the correctness of flooding with feedback can be used.

AN ASYNCHRONOUS BUILDING BLOCK

This recurring idea that building trees on G asynchronously can be used to anchor asynchronous computations for proper termination signaling can be made more general and be applied to certain portions of the computation only. That is, it is possible to structure the tree-building procedure in such a way that it becomes a building block for the construction of more complex distributed algorithms. We specify such a building block now and use it to construct the algorithm in a later section as an example of its use.

Let N_i denote the set of neighbors of node i in G . Let N_i^- be a subset of N_i . Also, let S_i and T_i be Boolean conditions relative to node i , used respectively to indicate, when they become true, that node i is to be the sole initiator of the construction of a tree rooted at it, and that node i , not being the initiator, is to participate in such a construction as it is reached by its messages. The following three actions

indicate how to grow and contract such a tree. We let node k be the assumed initiator of the algorithm and root of the tree. We use the same *msg* and *ack* messages as in the section on “The Quintessential Asynchronous Algorithm.” Counter c_i is also used at each node i as in that section.

4. *Initiation at node k when S_k becomes true*—If $N_k^- \neq \emptyset$, then send *msg* to all nodes in N_k^- and increment c_k by $|N_k^-|$.
5. *Upon the reception of msg from node j at node i* —If $i \neq k$ and receiving *msg* has caused T_i to become true, and also $N_i^- \neq \emptyset$, then send *msg* to all nodes in N_i^- , increment c_i by $|N_i^-|$, and let $p_i = j$. Otherwise, send *ack* to node j .
6. *Upon the reception of ack at node i* —Decrement c_i and check whether $c_i = 0$. In the affirmative case, conclude that the tree has contracted back onto its root if $i = k$, or send *ack* to p_i if $i \neq k$.

Actions 4 to 6 promote the growth of a tree on G that is rooted at node k . Its creation starts when S_k becomes true and is joined by every node $i \neq k$ for which T_i becomes true as *msg* messages arrive and $N_i^- \neq \emptyset$. Its contraction is started concurrently at every node $i \neq k$ for which T_i never becomes true or $N_i^- = \emptyset$, and also as nodes receive copies of *msg* other than the first, and continues with the ensuing sending of the *ack* messages. Obviously, letting $N_i^- = N_i$ for all i and setting T_i to become true for all $i > 1$ as the first *msg* arrives yields the asynchronous algorithm for flooding with feedback. In this case, $msg = ack = I$ and the flooding starts when S_1 becomes true.

EVENTS AND GLOBAL STATES

The design of an asynchronous algorithm must be resilient to any degree of the uncertainties that underlie the asynchronous model. Such uncertainties refer to the fact that local clocks are in no way correlated to one another, and also to the unpredictable delays that messages may undergo as they are transmitted on the edges of G . What this amounts to is that different executions of the same asynchronous algorithm may, from the local standpoint of a certain node, entail the reception of a different sequence of messages for each execution and therefore a different sequence of actions as well. Characterizing what is meant by an execution precisely is then crucial, as it affects directly the conception of certain asynchronous building blocks and also allows complexity measures to be defined correctly.

In what follows, and also in some of the forthcoming sections, we use a directed graph D in lieu of the undirected graph G we have been using. The nodes of D are the same as those of G , and its edges, by contrast, indicate the possibility of unidirectional communication between the nodes. We do this substitution for the sake of generality, since an undirected graph with the bidirectional-channel interpretation we have ascribed to the edges of G is equivalent to the particular case of D that has two directed edges between every two nodes that are neighbors in G , one in each direction. We let c denote the number of directed edges in D .

Our definition of an execution of an asynchronous algorithm is based on the seminal work of Lamport (1978). For an asynchronous algorithm A , we define an execution of A to be a set V_A of so-called events (Figure 1(b)). An event v is a sextuple containing the following elements:

$node(v)$ is the node of D at which v happens;
 $time(v)$ is the time, as given by the local clock of $node(v)$, right after the occurrence of v ;
 $in\_msg(v)$ is the message, if any, whose reception at $node(v)$ triggers the occurrence of v ;
 $Out\_msgs(v)$ is the set of the messages, if any, that $node(v)$ sends out as a consequence of the occurrence of v ;
 $p\_state(v)$ is the local state of $node(v)$ that precedes the occurrence of v ;
 $s\_state(v)$ is the local state of $node(v)$ that succeeds the occurrence of v , that is, at time $time(v)$.

Clearly, this definition of an event captures the essential nature of an asynchronous algorithm, allowing for the first actions of initiators and for the subsequent processing by all nodes as they react to the reception of individual messages.

The events in V_A are obviously not independent of one another. In fact, the definition of the following binary relation, denoted by B , is quite natural. For $v, v' \in V_A$, we say that $(v, v') \in B$ if one of the two following possibilities holds: either $node(v) = node(v')$ and $time(v) < time(v')$ with no intervening events between them; or $node(v) \neq node(v')$ and $in\_msg(v') \in Out\_msgs(v)$. In other words, B characterizes the situations in which v is an immediate predecessor of v' , either occurring in immediate succession at the same node, or occurring at different nodes, provided the message that triggers the occurrence of v' is sent as a consequence of the occurrence of v .

This relation B gives rise to two important entities. The first is an acyclic directed graph, called the precedence graph of execution V_A ; its node set is V_A and its edge set is B (Figure 1(c)). The second important entity is the transitive closure B^+ of B , which is known as the happened-before relation; B^+ is a partial order on V_A and allows the precise definition of the past of an event v as $Past(v) = \{v' \in V_A \mid (v', v) \in B^+\}$ and of v 's future as $Future(v) = \{v' \in V_A \mid (v, v') \in B^+\}$. It also allows concurrent events in V_A to be defined precisely: $v, v' \in V_A$ are concurrent if neither $(v, v') \in B^+$ nor $(v', v) \in B^+$.

The asynchronous model, by definition, precludes the precise treatment of global properties in time-related terms. This, of course, is because of the absence of a global clock, but the need remains for us to be able to refer to global properties. For example, the termination property that is detected as, in the algorithm of the section on "The Quin-tesential Asynchronous Algorithm," node 1 sets c_1 to 0 is a global property that makes sense even if we eliminate all *ack* messages from that algorithm: all this elimination achieves is that node 1 is no longer capable of detecting termination, but the notion of termination remains valid, and it is legitimate for us to want to refer to it globally. The way to achieve this is by defining precisely what a global state of the execution V_A is. We present this definition in two stages.

In the first stage, we first partition V_A into the sets $V_A(1), \dots, V_A(n)$, where $V_A(i)$ is the set of events v for which $node(v) = i$. Then we further partition each $V_A(i)$ into $V_A^1(i)$ and $V_A^2(i)$ in such a way that $time(v) < time(v')$ for any $v \in V_A^1(i)$, $v' \in V_A^2(i)$. If we now regroup these sets into $V_A^1 = \cup_i V_A^1(i)$ and $V_A^2 = \cup_i V_A^2(i)$, then the new partition of V_A into V_A^1 and V_A^2 can be seen to define a global state of the system represented by the directed graph D . In this global state, the local state of node i is either its initial state (if $V_A^1(i) \neq \emptyset$) or $s\_state(v)$, where v is the event in $V_A^1(i)$ for which $time(v)$ is greatest. The global state also includes messages in transit on the edges of D ; these are the messages $in\_msg(v')$ such that $v' \in V_A^2$ and $in\_msg(v') \in Out\_msgs(v)$ for some $v \in V_A^1$.

Global states defined in this way can be easily seen to give rise to causal inconsistencies with respect to the partial order B^+ . In the definition's second stage, we then complete it by requiring that $Past(v) \subseteq V_A^1$ for all $v \in V_A^1$ (an equivalent statement of this requirement is that $Future(v) \subseteq V_A^2$ for all $v \in V_A^2$). We sometimes refer to V_A^1 as the global state's past and to V_A^2 as its future. Global states are illustrated in Figure 1(d).

Vector Clocks and Beyond

This theory has been extended by the incorporation of several other time-related notions for asynchronous algorithms. These extensions can be found in the articles collected by Yang and Marsland (1994) and also elsewhere (e.g., Drummond and Barbosa 2003). One of the strongest motivations has been the design of algorithms for detecting various types of global predicates, such as the ones of Drummond and Barbosa (1996). We close this section by briefly discussing the notion of a vector clock. The vector clock of node i at time $time(v)$, with v such that $node(v) = i$, is the size- n one-dimensional array K_i whose j th component is

$$K_i[j] = \begin{cases} time(v), & \text{if } j = i; \\ time(pred(v)), & \text{if } j \neq i, \end{cases}$$

where $pred(v)$ is the latest predecessor of v at node j , that is, the event $v' \in V_A(j)$ such that $(v', v) \in B^+$ for which $time(v')$ is greatest (if no such event exists, then we assume $time(pred(v)) = 0$). It is easy to see that there exists a global state of V_A of which K_i is the node-state part. Also, if every node attaches its current vector clock to all messages it sends, and furthermore updates its vector clock, whenever it receives a message, to the component-wise maximum of the vector clock that comes in the message and its own, then the result remains a valid vector clock. The extension of vector clocks to higher-dimensional matrix clocks follows similar principles and allows for consistent local representations of arbitrary-depth portions of an event's past in execution V_A .

OTHER ASYNCHRONOUS BUILDING BLOCKS

In addition to the tree-constructing asynchronous building block of the section on "An Asynchronous Building Block," two others are generally regarded as being just as fundamental. We discuss them next.

Leader Election

In the section on “Models of Computation,” we introduced the leader-election problem as the problem of finding the node whose identification is the minimum. The problem is well posed, because we assumed that all nodes have distinct identifications totally ordered by $<$ and that all nodes are candidates initially. In this section we consider a more general definition of the problem: not only is G no longer assumed to be a complete graph, but also not all nodes are candidates initially. In addition, the problem does not ask for the candidate of least identification, but asks instead that all nodes agree on some candidate's identification.

When posed like this, the problem is very closely related to the problem of finding a minimum-weight spanning tree on G when edge weights are all distinct and totally ordered by $<$ (and hence G has a unique minimum-weight spanning tree). The reason that the two problems are so close to each other is that, in several solutions of the latter problem (Gallager, Humblet, and Spira 1983; Chin and Ting 1990), when the minimum-weight spanning tree is finally obtained, we automatically have a core edge whose end nodes, having distinct identifications, can decide between them which one becomes leader if at least one of them is a candidate. If neither is a candidate, then they can take upon themselves the task of deciding which of the candidates is to become leader. Obtaining their identifications and disseminating through all nodes the leader's identification is achieved rather simply by computing exclusively on the edges of the tree. The entire procedure, including finding the tree, can be designed so that the number of messages it requires is $O(m + n \log n)$.

It then remains for appropriate weights to be set for all edges of G . Any set of distinct weights ordered by $<$ will do, including the adoption of the ordered pair $(\min\{id_i, id_j\}, \max\{id_i, id_j\})$ as the weight of the edge between nodes i and j . In this case, weights are ordered lexicographically by $<$, and this is how comparisons are to be made as the minimum-weight spanning tree is built.

Global-State Recording

Consider an arbitrary execution V_A of an asynchronous algorithm A . Let X_A^1 , X_A^2 and Y_A^1 , Y_A^2 be distinct partitions of V_A that define global states as explained in the section on “Events and Global States.” We say that the latter of these global states is in the future of the former one if $X_A^1 \subset Y_A^1$ (equivalently, if $Y_A^2 \subset X_A^2$). Now let P be a global predicate on execution V_A . We say that P is stable if P is true of all global states that are in the future of a global state of which P is true. One example of stable predicates is termination, which is true of a global state if and only if all nodes are idle and all edges are empty in that global state.

One possible approach to the detection of stable predicates is to repeatedly record global states of V_A until one is found of which the predicate is true. The ability to make such recordings is then crucial, and we now review an asynchronous algorithm to do it. As in the section on “Events and Global States,” for the remainder of this section we revert to using the directed graph D in lieu of the undirected G .

The algorithm we give is the one of Chandy and Lamport (1985). Like all algorithms for recording global states, it is to be viewed as a separate computation that is superimposed on the computation whose execution is V_A (this execution is then referred to as a substrate). Even though A and the recording algorithm are separate entities, it is the interaction between them that allows for the recording of global states of V_A . So the two algorithms share the nodes of D (whose processing capabilities are split between the two as their actions are executed atomically) and also its edges.

Similarly to our earlier practice, we refer to each message of the substrate generically as *msg*. The recording algorithm uses *marker* messages exclusively, even though it also handles, without interpreting them, the *msg* messages. During recording, each node is responsible for recording its own local state and also the states, in the form of sequences of messages, of all edges that in D are directed toward it. We use $Msgs_i(j)$ to denote the sequence, initially empty, into which node i records messages it receives from j if (j, i) is a directed edge of D .

The recording admits any number of concurrent initiators. An initiator records its own local state and sends *marker* on all its outgoing edges. Any other node, upon receiving the first *marker*, does the same. From then on, node i (initiator or otherwise) monitors the *msg* messages it receives: if (j, i) is an edge of D , then every *msg* received from node j before a *marker* is received from that same node is appended to $Msgs_i(j)$.

This algorithm, evidently, is nothing but the obvious extension to directed graphs of the flooding algorithm of the section on “Models of Computation,” naturally with the necessary provisions for node- and edge-state recording. If D is strongly connected, then assuredly all nodes participate in the recording and, overall, exactly c *marker*'s are sent. It is also possible to prove that, if in addition D 's edges deliver messages in the first-in, first-out (FIFO) order, then all the information the algorithm records does indeed constitute a global state. In this global state, all (and only) messages recorded in $Msgs_i(j)$ have the following property: they were sent before node j 's recording of its own local state and received after node i 's. This property is the key to extending the algorithm to the case of non-FIFO message delivery.

AN EXAMPLE

We draw this section's example from the area of distributed computations for resource sharing. In this case, the nodes of G compete with one another for the use of shared resources, and we assume that the sharing policy they follow defines a dynamic subgraph of G that reflects, along the computation's global states, the wait of nodes for one another. Even though G is an undirected graph, this subgraph has directed edges: if the directed edge (i, j) is part of it in a certain global state, then in that global state node i is blocked and waiting for a signal from node j to help release it. We denote this subgraph of G by W . By the nature of W , its sinks (if any) are the only unblocked nodes, and the possibility of deadlocks is a reality.

A rich set of graph-theoretic concepts exists for the treatment of deadlocks in W (Barbosa 2002). In particular,

since the existence of a deadlock in W is a stable property, recording a global state of the resource-sharing computation and checking the corresponding (static) W for the occurrence of some sufficient condition for deadlocks to occur is a common approach (we refer the reader to the example given by Misra and Chandy (1982), which is a clever, albeit concise, application of the template of the section on “The Quintessential Asynchronous Algorithm”).

One example that illustrates the use of the tree-constructing building block of the section on “An Asynchronous Building Block” is the following (Bracha and Toueg 1987). Suppose that the resource-sharing computation is such that node i must receive at least x_i signals from its out-neighbors in W to be released. In order for node 1 to detect whether it is in deadlock according to a recorded W , it first builds a tree following actions 4 to 6 with: $k = 1$, S_1 becoming true when node 1 suspects it is in deadlock, T_i becoming true when node $i \neq k$ receives the first message, and finally N_i^- the set of out-neighbors of node i in W . This tree unfolds out from node 1 through the nodes’ out-neighbors. If any sinks are reached, then each one builds another tree concurrently with the other sinks, before allowing the original tree to contract. Each sink-rooted tree follows actions 4 to 6 with: k the corresponding sink’s number, S_k becoming true when node k is reached by the messages constructing the original tree, T_i becoming true when (nonsink) node $i \neq k$ has just received x_i of the messages used to expand the sink-rooted trees, and finally N_i^- the set of in-neighbors of node i in W . After the original tree contracts back on node 1, it decides for deadlock if and only if T_1 is false (note that T_1 is defined only for the sink-initiated tree constructions). This algorithm requires no more messages than twice the number of edges in W . An illustration is given in Figure 2.

COMPUTATIONAL COMPLEXITY

So far we have only superficially touched the issue of computational complexity. In the field of distributed computing, the complexity measures of interest are the time for completion of the algorithm and the overall number of messages used. In previous sections we have only given complete complexity figures for the two simple synchronous algorithms of the section on “Models of Computation”; for all asynchronous algorithms, we limited ourselves to discussing the number of messages used. We now give precise definitions in both cases; we concentrate on the case of worst-case figures, which is by far the most common, but it should become clear that extensions to average-case figures are straightforward. In what follows, we let $\mathbf{G}$ denote the class of all graphs for which a certain algorithm is designed (e.g., all connected graphs, all rings, etc.).

For an asynchronous algorithm A and a graph $G \in \mathbf{G}$, let $V_A(G)$ be the set of all possible executions of A on G . In the section on “Events and Global States,” we emphasized the possibility of multiple distinct executions of A as they stem from the inherent unpredictability of the asynchronous model, but clearly there can be variation due to differences in initial local conditions and also to probabilistic decisions. We denote the number of messages required for running A on G during execution V_A by $Messages(A, G, V_A)$. Clearly, assessing this number correctly

Figure 2 In the W of part a, x_i is equal to the number of out-neighbors of node i for $i \in \{1, 2, 3, 5, 6\}$. Part b shows one possibility for the tree rooted at node 1, at the stage in which its leaves are the sinks of W (nodes 3 and 5). For $x_4 = 2$, parts c and d show, respectively, the edges of W traversed by messages of the tree-building procedures started by nodes 3 and 5 (we assume that timing is such that node 4 is reached by a message from node 5 before being reached by one from node 3, and likewise node 1 from node 6 before node 4). Node 1 is reached once in each case (hence x_1 times overall) and concludes that it is not in deadlock in W . For $x_4 = 3$, on the other hand, the traversed edges are those shown in parts e and f, respectively for the tree-building procedures started by nodes 3 and 5 (timing conditions are in this case irrelevant). Node 1 is only reached once, and only by the edges that correspond to the latter procedure (hence less than x_1 times overall), so it concludes that it is in deadlock in W . For the sake of clarity, we omit from parts c and e any indication of the trees rooted at node 3, and similarly for parts d and f with respect to node 5.

is a matter of counting message exchanges during the execution. The worst-case message complexity of algorithm A , denoted by $MCompl(A)$, is defined as

$$MCompl(A) = \max_{G \in \mathbf{G}} \max_{V_A \in V_A(G)} Messages(A, G, V_A).$$

That is, for fixed G we first find the number of messages exchanged during the execution of A on G that requires the most messages. Then we take the greatest of these numbers over $\mathbf{G}$. Naturally, the resulting figure depends on the parameters associated with at least one $G \in \mathbf{G}$, such as n , m , $diam(G)$, or possibly others; here, and henceforth, we refrain from indicating this dependency explicitly for notational ease. All message complexities we have given heretofore in the chapter for asynchronous algorithms conform to this definition, as one may easily check.

A completely analogous definition can be given for the worst-case time complexity of A , which we denote by $TCompl(A)$:

$$TCompl(A) = \max_{G \in \mathcal{G}} \max_{V_A \in V_A(G)} Time(A, G, V_A),$$

where $Time(A, G, V_A)$ is the time required for running A on G along execution V_A . The absence of a global clock in the asynchronous model requires that we approach the definition of this latter quantity with care. For cases in which the guarantee of a single initiator exists, a possibility one might think of would be to let this time be as given by the initiator's local clock. But this approach is avoided in general, because it makes the eventual time complexity depend on a specific clock and on the rate at which time progresses according to that clock.

A better approach is to recognize that the time expended by an asynchronous algorithm is determined primarily by the causal flow of messages on G during execution. For this reason, we assume local computation to take no time (just as in the synchronous model) and let $Time(A, G, V_A)$ be given by the length of the longest causal chain in V_A involving the reception of a message and the sending of another as a consequence. More precisely, we take the precedence graph of execution V_A and assign weights to each of its edges: either 1 (if it is a message-related edge) or 0. Then we let $Time(A, G, V_A)$ be the length of the longest weighted directed path on the precedence graph of V_A .

As we look back on the asynchronous algorithms seen previously in the chapter, we see that the flooding-based ones (both the two of the section on "Models of Computation" and the algorithm for global-state recording) all have an $O(n)$ worst-case time complexity. We also remark that it is possible to design an asynchronous algorithm for minimum-weight spanning trees that runs in $O(n \log^* n)$ time in the worst case ($\log^*$ denotes the number of successive applications of the log operator required to yield a number less than 1). As for the deadlock detection algorithm of the section above in which we give an example, it runs in $O(w)$ time in the worst case, where w is the number of nodes of W .

We finalize by pointing out that the case of synchronous algorithms is entirely analogous, provided we understand that the possibility of multiple executions has now nothing to do with the model of computation. Furthermore, the time required to run a synchronous algorithm S on G along a certain execution can be assessed by simply counting pulses. Henceforth, we let $MCompl(S)$ and $TCompl(S)$ denote, respectively, the worst-case message and time complexities of S .

SYNCHRONIZERS

As we remarked in the section on "Models of Computation," the synchronous model is unrealistic. The reason that it remains important despite this fact is that designing algorithms under its assumptions is often considerably simpler than designing for the asynchronous model. For example, the synchronous algorithm given in the previously mentioned section for numbering the nodes of G breadth-first is amazingly simple; an asynchronous

algorithm, by comparison, would require considerable additional control and be significantly more complex.

But what really guarantees the place of the synchronous model in the study of distributed algorithms is the certainty that every synchronous algorithm can be correctly and automatically translated into an equivalent asynchronous one. This is achieved by transforming the operation of the synchronous algorithm at each pulse $s \geq 0$ into a fragment of an asynchronous algorithm. The desired asynchronous algorithm is obtained by piecing together these fragments for all values of s . Such fragments are known as synchronizers (Awerbuch 1985).

Let $Sync$ be a synchronizer and suppose its worst-case message and time complexities (the latter in the asynchronous sense) per pulse are $M(Sync)$ and $T(Sync)$, respectively. Suppose also that initializing $Sync$ requires $M_0(Sync)$ messages and $T_0(Sync)$ time at most. From the general description we have given so far of a synchronizer, it is clear that the asynchronous algorithm A resulting from transforming a synchronous algorithm S via synchronizer $Sync$ has worst-case message and time complexities given, respectively, by

$$MCompl(A) = MCompl(S) + M_0(Sync) + TCompl(S)M(Sync)$$

and

$$TCompl(A) = T_0(Sync) + TCompl(S)T(Sync).$$

The essential property that needs to be guaranteed before a node executes its portion of the synchronous algorithm corresponding to pulse $s + 1$ for $s \geq 0$ is that all messages sent to it at pulse s have reached it. This can be taken for granted when the assumptions of the synchronous model are in effect, but lifting them requires special actions to ensure that the property continues to hold. Let us call a node safe with respect to pulse s when all messages it sends during that pulse have reached their destinations. Clearly, in order for a node to proceed to pulse $s + 1$ it suffices that all its neighbors be safe with respect to pulse s . The task of a synchronizer is to convey this safety information to all nodes for each pulse. We start by having all messages of S explicitly acknowledged by an *ack* message; clearly, this has no effect on $MCompl(S)$ or, provided no *ack* is ever withheld for later transmittal, on $TCompl(S)$.

Basic Synchronizers

The first basic synchronizer is called α and conveys the safety information directly between neighbors. When a node has received all *ack* messages corresponding to the messages it sent in pulse s it sends a *safe(s)* message to all its neighbors. Upon receiving a *safe(s)* message from all its neighbors, a node may proceed to pulse $s + 1$. We clearly have $M(\alpha) = O(m)$ and $T(\alpha) = O(1)$. Initializing synchronizer α requires that G be flooded with a signal for all nodes to start pulse 0, and so we have $M_0(\alpha) = O(m)$ and $T_0(\alpha) = O(n)$. Another basic synchronizer, called β , requires a rooted tree to have been built on G beforehand. The root floods the tree, with feedback, with successive signals for the nodes to execute the succession of pulses.

The feedback progresses past a node only when that node has received *ack* messages for all messages it sent during the current pulse. Clearly, $M(\beta) = T(\beta) = O(n)$. As for $M_0(\beta)$ and $T_0(\beta)$, they depend on the complexities of electing a leader (cf. the section on “Other Asynchronous Building Blocks”).

A Parameterized Synchronizer

Synchronizers α and β may be combined in a parameterized way to yield another synchronizer. This combination requires the establishment on G of a rooted forest with a number k of trees and of preferential edges between neighboring trees. Synchronization takes place at two levels: inside each tree it works as synchronizer β ; at a higher level, at which we consider a graph whose nodes are the trees’ roots and whose edges join roots between which a simple path exists in G containing only tree edges and one preferential edge, it works as synchronizer α . If the largest tree has $O(f(G))$ edges, the number of preferential edges is $O(g(G))$, and moreover the greatest tree height is $O(h(G))$, then we have, letting γ denote this hybrid synchronizer, $M(\gamma) = O(kf(G) + g(G))$ and $T(\gamma) = O(h(G))$. The synchronizer γ of Awerbuch (1985) has $M(\gamma) = O(kn)$ and $T(\gamma) = O(\log n / \log k)$. It also has $M_0(\gamma) = O(kn^2)$ and $T_0(\gamma) = O(n \log n / \log k)$.

ADDITIONAL TOPICS

So far in this chapter we have aimed at characterizing what we judge to be the core aspects of the design and analysis of distributed algorithms. But progress has also been made along several other important avenues that are relevant from both a theoretical and an applications-related perspective. We devote this section to highlighting some of them.

Theoretical Aspects

Lower Bounds and Impossibility Results

An important issue that has persisted through the entire development of the field of distributed algorithms has been that of identifying what can and what cannot be computed distributedly, while asserting the minimum message and time complexities of the feasible computations whenever possible. Establishing such results depends on several factors, including the model of distributed computing that is assumed, the system’s topology, the existence of distinct identifications for all nodes, and the possibility of failures. We refer the reader to the survey article by Fich and Ruppert (2003) for a comprehensive treatment.

Computing on Anonymous Systems

Anonymity means that the assumption of distinct node identifications does not hold. Although it may be argued that studying distributed computations on anonymous systems has in the past had little practical import, assuming anonymity is theoretically interesting because it highlights the influence of model- and topology-related characteristics on the possibilities of distributed computing. Electing a leader, for example, is naturally expected to be impossible under anonymity. What is curious, though, is that other

problems that do not explicitly rely on node identifications also exist that cannot be solved distributedly if the system is anonymous. Several of the pertinent results refer to the consistent computation of functions from distributed inputs (Attiya, Snir, and Warmuth 1988; Attiya and Snir 1991; Yamashita and Kameda 1996), but there has also been recent interest in the impact of anonymity on other distributed tasks (e.g., routing in wireless sensor networks; cf. Dutra and Barbosa 2006).

Topological Awareness

Whenever a distributed algorithm is given for a graph G of unrestricted topology, the prevailing assumption in the field is that no node has built-in information on the structure of G . Such information can come only at the expense of messages and time, and this has to be weighed against any complexity-related advantage one may expect from knowing it locally. One interesting line of research has addressed the question of how to give nodes built-in information that, while still essentially local, has the potential of providing the desired topological awareness. Flocchini, Mans, and Santoro (2003) survey the successful approach known as sense of direction, which is based on labeling edges (locally at each node) in a globally consistent manner.

Self-Stabilization

Throughout the chapter we have concentrated solely on systems that do not fail. The study of failures, however, is an important part of the field of distributed algorithms. One aspect of it is the design and analysis of asynchronous algorithms that, regardless of how local variables are initialized, necessarily converge to some global state satisfying a preestablished property. These are then infinite computations that require no initialization and are resilient to local-state corruption to a certain degree. The characteristic of necessary convergence to a desired global state is called “self-stabilization.” Its original introduction and also the first known examples are due to Dijkstra (1974); since then, the field has undergone considerable development (Dolev 2000).

Consensus Problems

These problems have a paradigmatic status in the study of failure-prone systems and ask that all nodes that do not fail reach some sort of agreement. In the asynchronous model, and considering node failures of the crash type only, the very influential study of Fischer, Lynch, and Paterson (1985) establishes the impossibility of agreement even if communication is fully reliable. In the synchronous model, by contrast, agreement can be reached even if we allow for the malicious (so-called Byzantine) failures in which nodes may fail by behaving unreliably instead of crashing (Pease, Shostak, and Lamport 1980; Lamport, Shostak, and Pease 1982), provided at least $2n/3 + 1$ of the n nodes do not fail. The reason for such a wide gap between what happens in the two models is that failure detection is trivial in the synchronous model but unattainable in the asynchronous model. However, in many real-world systems that do not adhere to the synchronous model,

reaching agreement seems to be a definite possibility, as in fact demonstrated by the known solutions that adopt some sort of partially synchronous model or randomization (Gärtner 1999). The current framework within which these issues are studied was inaugurated by the work of Chandra and Toueg (1996) and its precursors by the same authors, and is centered on the notion of a failure detector: an imperfect distributed oracle that embodies the desired assumptions of partial synchronism. An introduction to the subject has been given by Raynal (2005).

Correctness Proofs

Similarly to what happens in all algorithm-oriented research areas, many researchers in the field of distributed algorithms have striven for the definition of frameworks that may ultimately lead to automatic correctness proofs. Input/output (I/O) automata and the various abstract structures through which they are combined are an example (Lynch et al. 1994). Another example is UNITY, originally introduced by Chandy and Misra (1988), comprising a programming notation and an associated logic. Ongoing progress on UNITY can be tracked through the PSP Group at UT Austin (2003), for example.

A Unifying Theory

As we generalize the synchronous and asynchronous models to encompass the possibility of failures and also communication by shared memory, the question of whether a unifying theory of computability and complexity for distributed computing can be constructed arises naturally. The surveys by Lamport and Lynch (1990) and Gafni (1999) offer two views of the issue separated by nearly a decade. A reasonable conclusion from the evolution of the field in the meantime between the two surveys seems to be that a theory has begun to emerge that focuses on the properties of complete problems—in a sense similar to that in which certain decision problems are NP-complete—using the tools of combinatorial topology (cf. Rajsbaum 2004 for the key references). Whether such a theory will be consolidated or remain a largely inchoate body of knowledge is yet to be seen.

Applications

Resource Sharing

Resource-sharing computations such as the one we used as an example above not only raise the safety-related issues (such as deadlock) of that example, but also are a source of important questions related to liveness issues and to the essential nature of synchronization procedures other than the synchronization for safety of the section on “Synchronizers” (Barbosa 2002). Answering these questions has led to the design of distributed schedulers targeted at deadlock- and lockout-free resource sharing. Such schedulers are rooted in the combinatorial properties that underlie all resource-sharing constraints, as can be seen, for example, in the seminal work of Chandy and Misra (1984) and in its further characterizations (Barbosa and Gafni 1989) and generalizations (Barbosa, Benevides, and França 2001).

Computing on Wireless Networks

The current ubiquity of wireless networks, including mobile ad hoc and sensor networks, has prompted researchers in the field to a whole new class of challenges. Depending on the nodes’ degree of mobility in the network, even the seemingly simple task of determining their locations has required careful attention and resulted in the development of a special theory (Aspnes et al. 2006) to support the creation of location-independent algorithms, for example like the one for routing given by Fonseca et al. (2005). In a similar vein, for many of the envisaged applications of sensor networks it is expected that nodes will have to synchronize their local views of real time, and again special distributed algorithms, for which the works of Su and Akyildiz (2005) and Fan and Lynch (2006) provide the bases, will be needed. Of course, what prevents the direct use of the algorithms we have seen throughout the chapter is the dynamic character of G ’s topology. In such circumstances, even well-understood problems like determining a minimum-weight spanning tree distributedly may be impossible to solve exactly, which has motivated the first steps toward a theory of distributed approximability (Elkin 2004). Further applications-related considerations, like noisy environments and severe memory and processing limitations, also seem to be bringing the issues of anonymity and self-stabilization back to the fore (Angluin et al. 2005, Stably computable properties of network graphs; Angluin et al. 2005, Self-stabilizing population protocols).

Computing on Complex Networks

Networks like the Internet (and also several others; cf. Bornholdt and Schuster 2003 and Newman, Barabási, and Watts 2006) are examples of what we call a “complex network,” that is, a large-scale, unstructured network of essentially unknown topology. Asynchronous algorithms designed to work on a generic graph G work also on such networks, but the networks’ massive scale may lead to unacceptable complexity figures in the case of some algorithms. However, since the discovery that the Internet may be an instance of a random graph with known degree distribution (Faloutsos, Faloutsos, and Faloutsos 1999), the possibility has been opened up of designing asynchronous algorithms that take such a distribution into account and produce less costly approximations of the algorithms for generic G . Recent examples include probabilistic approximations of dissemination by flooding (Stauffer and Barbosa 2007), with applications (Stauffer and Barbosa 2006a), and also the probabilistic algorithm of Stauffer and Barbosa (2006b) to approximate the construction of a spanner (Kortsarz and Peleg 1998).

CONCLUSION

This chapter has concentrated on discussing the field of distributed algorithms from two main perspectives. The first perspective has been that of how to handle the notion of time under full asynchronism, and consequently how to approach the treatment of global properties. The second perspective has been that of designing asynchronous algorithms up from its constituent building blocks. Our treatment has included a discussion of some fundamental building blocks and also examples of their use.

It is important for the reader to bear in mind that the field is much broader than our limited selection of topics may have implied. The main role of the section on “Additional Topics” has been to single out and highlight some of the topics we have not treated in depth but are equally interesting and important.

ACKNOWLEDGMENT

GLOSSARY

Asynchronous Algorithm: A distributed algorithm for the asynchronous model.

Asynchronous Model: The model of distributed computing in which nodes are driven by independent, local clocks and messages suffer unpredictable, though finite, delays.

Atomic Action: The uninterrupted first action of an initiator, or the uninterrupted response to the arrival of a message, during a run of an asynchronous algorithm.

Event: A sextuple characterizing each atomic action of a run of an asynchronous algorithm.

Execution: A set of events characterizing a run of an asynchronous algorithm.

Global State: A two-set partition of an execution that is consistent with the happened-before relation.

Global-State Recording Algorithm: An asynchronous algorithm to record a global state.

Happened-Before Relation: A binary relation that gives the causal precedence among the events of an execution.

Initiator: A node that initiates a run of an asynchronous algorithm.

Leader-Election Algorithm: A distributed algorithm that identifies a unique node on whose identification all nodes agree.

Message Complexity: The worst-case number of messages required during a run of a distributed algorithm.

Synchronizer: An asynchronous-algorithm fragment for transforming a synchronous algorithm into an asynchronous one.

Synchronous Algorithm: A distributed algorithm for the synchronous model.

Synchronous Model: The model of distributed computing in which all nodes operate in lockstep with a global clock and messages suffer delays that are bounded by the duration between successive clock pulses.

Time Complexity: The worst-case time required for completion of a run of a distributed algorithm.

Tree-Constructing Algorithm: A distributed algorithm that constructs a tree rooted on its initiator.

INTRODUCTION

A distributed database system (DDBS) considers inter-connected sites, each containing a local database management system (DBMS), which interacts with the other sites through well-defined interfaces provided by the distributed database management system (DDBMS). It is widely recognized (Özsu and Valduriez 1999) that a key goal for DDBMSs is *transparency*: users must be able to interact with the system as if it were one single logical system.

Besides transparency, the expected benefits of DDBMSs compared to centralized DBMSs are the following:

- *Increased performance*: Data can be moved nearer to the points where they are mostly used and queries can be parallelized among several nodes.
- *Improved scalability*: When the amount of data increases, it can be easily further fragmented without having to change the rest of the system; moreover it is easier to integrate new databases.
- *Better reliability*: A fault in a node affects only that node, rather than the entire system.
- *Organizational structure is accurately reflected*: Data can be placed at the sites they relate to and be managed there, instead of being centrally managed.

However a DDBMS does not automatically grant these advantages; to benefit from them a number of issues must be addressed:

- *Architectural issues*: The component sites must be integrated into a single system. There are several options from which to choose in order to achieve this goal.

- *Distributed database design*: Additional issues are to be taken into account at the design stage with respect to central DBMSs. These include decisions about how relations should be partitioned (fragmentation) and where fragments should be stored (fragment allocation). Such decisions have a critical impact on query-execution times and thus dictate whether the DDBS actually improves performance.
- *Distributed query processing*: A DDBMS query processor must take into account the distribution of the data. This impacts the computation of query execution plans as well as query optimization, for which additional factors have to be considered (bandwidth, loads on the sites, etc.).
- *Reliability*: A DDBMS can improve reliability only if specific procedures have been designed for the cases in which one or more sites fail during the processing of a transaction.
- *Interoperability*: Such issues arise when the interconnected DBMSs are heterogeneous and/or have incompatible schemas.

The rest of this chapter is organized as follows. The next section describes the architectural alternatives for DDBMSs. Then we discuss the design issues specific to these systems. The following section outlines the topic of distributed query processing, and the next deals with the problem of reliability within DDBMSs, followed by a discussion of DDBMS interoperability. We then discuss Grid computing, more precisely Grid data management capabilities and the way they can be used to build and operate distributed databases. Finally, a summary of the subject is presented.

DISTRIBUTED DATABASE MANAGEMENT SYSTEMS ARCHITECTURES

Typology of Architectures

From an architectural point of view, DDBMSs can be characterized on the basis of three dimensions:

1. *Distribution* of data in the global system
2. *Autonomy* of the individual sites
3. *Heterogeneity* of the sites comprising the system

The resulting possibilities can be graphically displayed as a three-dimensional cube (see Figure 1). Each point corresponds to an architecture and represents its characteristics in the three dimensions. Let us first consider the alternatives for each dimension.

The possible options with respect to autonomy are:

1. *No autonomy*: The sites are tightly integrated and not capable of functioning independently.
2. *Partial autonomy*: The sites can function independently; however, the way they process queries is affected by cooperation. In this setting, the sites generally know about the existence of one another.
3. *Full autonomy*: The sites are fully independent, unaware of each other and unaffected by others.

The possible options with respect to distribution are:

- *No distribution*: All the data are located at a single site.
- *Partial distribution*: The data are distributed across some, but not all sites. A typical case is when participating machines are divided into servers, which hold data and process queries, and clients, which hold no data and access them only through queries to the servers.
- *Full distribution*: The data are spread across all sites. There is no distinction between the sites.

Figure 1: Dimensions of DDBMSs architectures; adopted and modified from Öszu and Valduriez (1999)

The possible cases in terms of heterogeneity are:

- *Homogeneity*: All machines and all sites are similar and connected through a homogeneous network. Minor differences in features that do not directly affect query processing are nevertheless possible.
- *Heterogeneity*: A system is considered heterogeneous when at least two sites differ in some characteristic that influences query processing. Heterogeneity factors include hardware architectures, operating systems, data managers, query languages and network access characteristics. Another heterogeneity factor is the existence of incompatible schemas in the component databases.

The main types of DDBS architectures with respect to these dimensions are:

- *Client/server*: No autonomy, partial distribution, homogeneity
- *Peer-to-peer*: Partial autonomy, full distribution, homogeneity
- *Multidatabases*: Full autonomy, full distribution, heterogeneity; *federated databases* are a semi-autonomous variant of multidatabases.

An important feature of DDBMSs architectures is the way they integrate separate databases so that they can be presented to users as a single database. One possibility is to create a global schema (the global conceptual schema, GCS) out of the local schemas. This issue is discussed in more detail in the section “Distributed Databases Interoperability.”

Client/Server-Based Architectures

Client/server architectures for DDBSs come in two variants: multiple clients/single server, or multiple clients/multiple servers.

The single server architecture is similar to a centralized system. The only significant difference is that clients usually access the server through a wide-area network instead of a local network, which puts more emphasis on the need for clients to process a part of the queries locally.

The multiple servers/multiple clients architecture has two different configurations. In the first case, each client is tied to a “home server,” to which it sends its queries. This server acts as a gateway to the other servers. The servers are therefore not fully autonomous as they need to cooperate when queries involve multiple servers. The clients are lightweight, because they can access their home server as in a single-server scenario. The communication between the servers is then of peer-to-peer nature, since each server can act both as a client (as a home server) and as a server (when processing queries from another server).

In the second case, each client directly contacts all servers involved in a query. In this case, the servers are fully autonomous, as they only receive queries. The clients are thick, because they need to have the capability to decompose queries into sub-queries (each sub-query being directed toward one server) and to reassemble the results.

Peer-to-Peer–Based Architectures

A peer-to-peer (P2P) system is an open-ended network of distributed computational peers, in which each peer can be both a client and a server—that is, it can provide and consume services or resources (see *Peer-to-Peer Network Architecture* and *Peer-to-Peer Network Applications* for more detail on P2P computing). There is no central authority in the network. Peers are autonomous, as they can freely decide the amount of data they make available, and enter and leave the system as they see fit (Schoder, Fischbach, and Schmitt 2005). P2P technology is mostly known for its use for distributed object sharing; however, it can also be used to serve as a foundation for the architecture of a DDBMS. As noted above, the system is autonomous per P2P definition (but only partially autonomous, as query processing requires cooperation between the peers), fully distributed, and homogeneous (in the sense that all peers communicate through identical P2P software, possibly hiding lower-level heterogeneity between them).

The mapping of P2P technology to DBMSs is not straightforward, as P2P systems lack a number of data management capabilities, such as managing complex data objects, content update, data semantics, and relationships between data (Roshelova 2004).

Especially, the existence of a global schema cannot be assumed because it would conflict with the autonomy of the peers. One solution to this problem is the mapping of local schemas on-the-fly during querying: query processing includes a schema-matching step in which schemas compatible with that of the query are looked for (Siong Ng, Ooi, and Zhou 2003). Alternatively, peers can coordinate themselves with their neighbors by mapping each others' schemas, new mappings being discovered via transitive relationships (Serafini et al. 2003).

Other problems related to peer-to-peer architectures include information redundancy, and the fact that the correctness and completeness of query results cannot be guaranteed (Ooi, Shu, and Tan 2003). At the time of the writing of this book, much of these remain open research issues, and productive peer-to-peer DBMSs are not available.

Multidatabases

Multidatabase systems correspond to the case in which a DDBMS is built on top of several existing DBMSs. In this case, heterogeneity is typically very high: operating systems, data formats, query languages and database manager software can all be different.

Given the nature of multidatabases, schema integration is a very important feature for allowing and optimizing query processing. This problem is described in more detail in the section on “Distributed Databases Interoperability”.

Such systems can be further divided in two categories (Bright, Hurson, and Pakzadd 1992):

- *Global schema multidatabases*: A GCS is created and maintained by the distributed system; local DBMSs are unaware of the existence of each other, remaining completely autonomous. Queries are aimed at the GCS and translated into sub-queries, each of which concerning a single database.
- *Federated database systems*: In a federated system, each DBMS defines an export schema which represents the

structure of the data it makes available to others. The queries are defined with respect to an import schema created by integrating several export schemas. These systems do not make use of a permanent GCS.

Comparison of the Architectures

Client/server-based systems are very widely used. They have several advantages:

- Users and database administrators are usually familiar with client/server technology.
- The technology is mature, and performance is known to be good.
- Many problems can be assimilated to similar ones of centralized DBMSs for which good solutions are known.

However:

- Client/server-based solutions cannot be applied in cases of heterogeneity: the participating databases must be fully compatible.
- A central point of administration is required.
- Adding and deleting nodes is a complex task.
- The participation to a client/server-based DDBMS has an influence on local query processing. The increased complexity might not be worth it for sites with mostly local queries.

Peer-to-peer–based systems have the following advantages:

- By design, there is no single point of failure.
- Administrative tasks are delegated to each node in the absence of central control. This can, however, turn into a problem in some cases, such as when updating the P2P software.
- Data are naturally replicated and cached locally, potentially improving performance.
- P2P systems scale well, as adding new nodes when needed is straightforward.

Their disadvantages are:

- The dynamic nature of the peers can be problematic, as it cannot be guaranteed that a node is available at a given moment.
- P2P systems are not adapted to all applications. For instance, when a node is not connected, its data are not available. This imposes limitations on the correctness and completeness of query results, which may be unacceptable for some applications.
- P2P databases are still a work in progress. Currently, there is no proof that a P2P DDBMS can deliver a performance similar to that of other architectures.

Multidatabase systems are difficult to compare with the other architectures because they provide solutions to cases in which other architectures cannot be used. These systems allow for the integration of very heterogeneous

databases without the need for modifying them. The main problem of these systems is that of schema integration, which can be a very complex task.

DISTRIBUTED DATABASE MANAGEMENT SYSTEMS DESIGN

General Design Strategies

Distributed database design strategies generally fall into two major categories (Ceri, Pernici, and Wiederhold, 1987): top-down design and bottom-up design.

The choice of a design strategy is usually mandated by context: a top-down approach can only be applied when building a DDBMS from scratch, while a bottom-up approach is required when legacy systems are to be integrated.

The top-down design approach starts by identifying the system requirements (top-level goals). Two steps are then performed in parallel: view design, in which the required interfaces of the system are defined, and conceptual design, which identifies the basic elements of the schema. This results in a global conceptual schema. This global schema is then broken into a number of local conceptual schemas (distribution design), which in turn are mapped to physical storage (physical design).

A significant disadvantage of this approach is that it is suitable only for DDBSs designed from scratch. Although this is probably the ideal case for designing optimal DDBSs, it is not so common: in many cases, the idea of a DDBMS comes as an afterthought in order to integrate already existing systems. The top-down approach also makes it difficult to add new databases to the system.

The bottom-up approach is very common in the case of multidatabases, in which a distributed database is to be built out of legacy systems that are already in use. Such a design starts by examining existing resources, especially the schemas of the databases to be integrated, in order to create a global conceptual schema out of them. The main issue here is that of database interoperability, discussed in more detail in its own section below.

The bottom-up methods essentially build on the previous design of the existing databases that they are willing to integrate. As such, they do not involve design decisions that are specific to distributed environments. Contrary to the top-down approaches. In consequence, the remainder of this section describes issues and solutions in the context of a top-down design.

Fragmentation

Definition

Fragmentation is the process of dividing a relation into subrelations. The rationale for fragmentation is that applications generally deal with subsets of relations (views) rather than with entire relations. In the context of distributed database systems, these subsets are therefore more convenient units of distribution than whole relations. More convenient units of distribution than whole relations (Özsu and Valduriez 1999). Cleverly defined fragments should also increase global performance, as they reduce the amount of irrelevant data to be dealt with and

transferred between sites, and allow parallel processing (Lim and Ng 1996). On the other hand, bad fragmentation design can lead to degraded performance if typical transactions make use of many fragments that are distributed over many different sites.

There are three types of fragments:

- *Horizontal fragments* are subsets of the tuples of a relation.
- *Vertical fragments* are subsets of the attributes of a relation.
- *Mixed fragments* are fragments that are both horizontally and vertically fragmented.

All fragments are associated with a query that allows retrieval of their content when applied to the original relation.

Rules of Correctness

The fragmentation process should not change the semantic nature of the database. This can be ensured by checking that its result complies to a number of specific rules of correctness, which are defined below. All subsequent definitions assume that a relation R has been divided into a set of fragments $F = \{R_1, R_2, \dots, R_n\}$. A data item is defined as a tuple for horizontal fragments and as a set of attributes for vertical fragments. The rules are the following:

- *Completeness*: For each data item d found in R , there should exist at least one R_i that contains d .
- *Reconstruction*: It must be possible to build a relational operator Δ such that

$$R = \Delta R_i, \forall R_i \in F$$

where Δ is the relational additive union operator for horizontal fragmentation, and the relational binary join operator for vertical fragmentation.

- *Disjointness*: A data item contained in a fragment must not appear in other fragments. There is an exception in the case of vertical fragmentation, for which the disjointness property applies only to non-primary key attributes. This is because a relation broken down vertically can only be rebuilt correctly from the fragments if they all include the primary key.

Horizontal Fragmentation Strategies

The horizontal fragmentation design choice can be divided into two categories:

- *Primary horizontal fragmentation*, in which tuples belong to fragments based on a predicate defined on the relation.
- *Derived horizontal fragmentation*, in which relations are partitioned with respect to the result of a predicate defined on another relation, e.g. the result of a join with another relation.

A horizontal fragmentation strategy must identify the “chunks” of the database that are accessed as units by

applications; usually such chunks can be defined by a *minterm* predicate, which can be written as a conjunction of simple predicates of the form $p : A\Theta K$, where A is a single attribute, K a value comprised in the domain over which A is defined and Θ a comparison operator. Identifying such chunks and minterm predicates yields a list of candidates for horizontal fragmentation.

The “optimal” fragmentation plan should then be chosen from among these candidates. Important criteria for this choice are *completeness* and *minimality* (Ceri, Negri, and Pelagatti, 1982). A set of simple predicates is complete if and only if the probability of access by all applications is the same for each tuple belonging to any minterm fragment defined according to it. Minimality means that all fragments defined by the set of simple predicates are accessed differently. If one of the simple predicates defines two fragments that are accessed exactly the same way by applications, then the fragmentation is not minimal, and this predicate should not be used as a basis for fragmentation.

Vertical Fragmentation Strategy

Vertical partitioning generally implies a very large number of alternatives, hence the use of heuristics rather than the search for optimal solutions. The main heuristics are variants of *splitting*, in which whole relations are considered one at a time in order to find a good fragmentation scheme with respect to previous access patterns (Navathe et al. 1984).

In order to choose a vertical fragmentation plan, the sets of attributes queried by each application and the frequency of occurrence of the corresponding queries must be considered. This information can be summarized in an *attribute affinity matrix* which to each couple of attributes (A, B) associates a relative measurement of how often A and B are used in conjunction in queries. This matrix constitutes the input of an algorithm that produces a fragmentation plan clustering attributes of high affinity.

Fragment Allocation

Fragment allocation is the choice of placement of the fragments on each site of the distributed system. In order to compute a proper allocation plan, the following information must be known beforehand:

- Information about fragments: size and associated query
- Information about applications: which fragments each application may access and/or update, number of read/update to each fragment for each query
- Information about sites: temporary and secondary storage and processing capacities
- Information about the network: bandwidth, average latency, etc.

Note that fragment allocation alternatives depend on the degree of replication allowed. The DDBMS can *forbid replication*, in which case each fragment resides at only one site, implement *full replication*, in which each fragment exists at each site, or more commonly, allow *partial replication*, in which replication is neither forbidden nor compulsory.

The allocation process consists of defining binary values for x_{ij} variables, where $x_{ij} = 1$ if fragment F_i is stored at site S_j and 0 otherwise.

An allocation model can then be defined. Such a model is defined by its goals; for example in the model detailed in Özsu and Valduriez (1999), the main goal is to minimize processing and storage costs, with acceptable response time as a secondary objective. The goals are modeled as functions; in the example, a total cost function is defined, which outputs the sum of query processing and storage costs, themselves modeled as functions. Functions are further refined until functions depending on decisions of fragment allocation are identified.

Such a model allows a quantitative evaluation of an allocation scenario, but does not directly give an “optimal” solution, as the problem is NP-complete (Özsu and Valduriez 1999). Therefore heuristics methods based on plausible rules that produce nonoptimal but reasonably good results have to be used.

DISTRIBUTED QUERY PROCESSING

The query processing problem is more complicated in distributed environments than in centralized ones, as a larger number of factors can play a role. In particular, the relations of a DDBS are typically fragmented and distributed over distant sites, which may increase response times to queries involving several fragments; this also increases the number of possible execution strategies from which to choose.

Planning a processing strategy for a distributed query is comprised of three steps, which are detailed in the next sections:

1. Query decomposition: The high-level query submitted by the client is decomposed into a set of operations expressed in the relational algebra (the algebraic query).
2. Data localization: The data that are accessed by the query is localized in the sites where they reside. The operations on global relations of the preceding step are transformed into operations on fragments.
3. Query optimization: This phase mainly amounts to choose the best execution plan with respect to pre-defined criterias.

Query Decomposition

Query decomposition is applied to global relations of the schema of a DDBS, and not to fragments. Its principles are, as such, identical for centralized and distributed databases (Kossmann 2000).

The process begins with the normalization of the high-level query. Usually, the submitted query is written in the structured query language (SQL); the main normalization operation is then the transformation of the WHERE clause. There are two types of normalized forms for such clauses, depending on whether precedence is awarded to the AND ($\wedge$) or to the OR ($\vee$) logical operator:

- The disjunctive normal form, where the clause is rewritten in the form:

$$(p_{1,1} \wedge p_{1,2} \wedge \dots \wedge p_{1,n}) \vee \dots \vee (p_{r,1} \wedge p_{r,2} \dots \wedge p_{r,m})$$

the p_{ij} 's being simple predicates and r, n, m constants.

- The conjunctive normal form, represented as follows using the same conventions:

$$(p_{1,1} \vee p_{1,2} \vee \dots \vee p_{1,n}) \wedge \dots \wedge (p_{r,1} \vee p_{r,2} \vee \dots \vee p_{r,m})$$

Rewriting a WHERE SQL clause in either form can be done easily using well-known transformation properties of the logical operators.

After the initial normalization, the query is analyzed, mainly to determine whether it is incorrect. Incorrect queries can either be type-incorrect or semantically incorrect. Type-incorrect queries use variables (attribute or relation names) not defined in the schema, or apply operators to attributes with which they are not compatible (e.g., a “greater than” operator applied to textual attributes). A query is semantically incorrect if some of its components do not contribute to the generation of the result. A typical example is that of a query on several relations in which no join clause has been specified.

The query is then parsed in order to eliminate redundancy. Simple predicates may need to be transformed using well-known idempotency properties in order to identify redundant statements.

The final step of the decomposition process consists of rewriting the query in the relational algebra—that is, in a form that uses only a set of operators (usually selection, projection, union, set difference, and cartesian product) applied to relations. This query can be represented as an *operator tree*, with the relations involved in the query as leaves, and with internal nodes corresponding to the relational operators; these operators are connected to their operands by edges.

Data Localization

The goal of the data localization process is to transform an algebraic query on relations into an algebraic query on fragments (Ceri and Pelagatti 1982).

As discussed in the section on “Distributed Database Management Systems Design,” fragments can be derived from the relations by applying fragmentation rules to them. Such rules can be written as relational queries. The reverse process is called a “localization program.”

In this context, a simple method of data localization is to substitute each relation by its localization program in the input query. The result is called the “generic query.” Although correct, the generic query is generally inefficient, and it is better to transform it using techniques specific to the type of fragmentation.

For horizontal fragments, the rules consist of identifying the parts of the generic query that produce empty relations. Typically, a selection or join operation applied to a fragment may contradict the fragmentation rule by which it is defined. Such operations can be written off the query. Similarly, in the case of vertical fragmentation, the query can be reduced by removing intermediary relations formed of projections with which the fragment has no common attribute.

Query Optimization

Though the previous steps have eliminated some obviously sub-optimal strategies, many query execution plans remain possible at this point. The goal of query optimization is to select one using a cost function as a choice criterion. Distributed query optimization in general is an NP-hard problem in the number of relations (Wang and Chen 1996), hence the motivation for using heuristics for selecting non-optimal but good plans.

At first a number of “good enough candidates” execution plans are generated. A large number of algorithms for this enumeration process have been proposed by the database community (Steinbrunn, Moerkotte, and Kemper 1997). Among them, the dynamic programming algorithm (Kossmann and Stocker 2000) is widely used, notably by popular commercial DBMSs. It consists in a dynamically pruning exhaustive search that constructs all alternative join trees by iterating on the number of relations joined so far. At each step, known rules are used in order to identify non-optimal trees and to prune them. The advantage of this algorithm is that it can guarantee to produce optimal or close-to-optimal plans with respect to the cost model that is used to assess the plans. Its problem is that it is of exponential computation time and space complexity, which makes it unsuitable for complex queries such as most of those submitted to a DDBMS. It can, however, be extended to use a simpler process for queries that are above a complexity threshold, producing “as good as possible plans” for complex queries with a reasonable computation time.

Choosing between the alternatives for the join trees in the query execution plan is a very important feature for a query optimizer. Indeed, the classical join operator being symmetrical, it is possible to permute the order of this join, and such permutations are known to have the most impact on the performance of the queries. In the case of DDBMSs, the normal way of processing a join between fragment A of site S_1 and fragment B of site S_2 is to transmit either A or B so that they are on the same site. Given the nature of distributed systems, the goal of join-ordering based optimization is to transmit the smallest operands of joins so as to minimize the network costs. This means that for complex queries with several joins, the size of the intermediate results involved in further joins in the query must be computed beforehand, which is generally a difficult and costly operation. Join operand ordering was the basis of the query optimizers of early experimental DDBMSs R and Distributed INGRES.

Semijoin programs were proposed as an alternative way of processing joins on fragments located on different sites (Bernstein et al. 1981). The semijoin of fragment A (of site 1) by fragment B (site 2) is defined as the subset of the tuples of A that participate in the join with B. The operator can be used to compute the join between A and B using the following sequences of operations:

1. The columns of A needed for the evaluation of the join predicate are sent from site 1 to site 2.
2. The set of tuples of B (noted B_j) that qualify the join is identified at site 2.
3. B_j is sent to site 1.
4. A is matched with B_j .

The argument for using semijoins in query execution plans is that they can reduce the amount of data that must be transmitted over the network. On the other hand, they increase the costs of processing, so they are traditionally considered useful when they induce communication costs savings that exceed the processing overhead that they create.

Candidate plans need to be evaluated using a cost model in order to determine the “best plan” with respect to predefined criteria. The main cost models for distributed queries are: the classic cost model and the response-time model.

The principle of the classic cost model is to estimate the resource consumption cost of every individual operation in the query and to add these costs up. The cost of an operation is composed of CPU, disk I/Os, and network consumption costs. The basic cost of a plan as evaluated by this model is thus its total resource consumption cost. The costs can be weighted according to the characteristics of the system (in order to take into account factors such as the average load on a site or the congestion on certain network links). Because it selects plans that use the least amount of resources, this model tends to increase the number of queries that can be performed simultaneously, maximizing site throughput.

The classic cost model does not favor intraquery parallelism; thus, it does not guarantee a minimal response time. Indeed, a plan with an optimal response time may be discarded if it consumes more resources. If response time is an important factor, it is advisable to use a different specific cost model (Ganguly, Hasan, and Krishnamurthy 1992). This model first computes the total resource consumption of each individual operation. Then, the total usage of every resource used by a group of operations that can be performed in parallel is calculated. The cost assigned to each group is defined as the maximum cost of all individual operations of the group. Intraquery parallelism is therefore taken into account, and the plan with the lowest expected time response should normally be selected. However, the model does not consider factors such as the load on each site, which may induce scheduling problems for heavily used sites and decrease the actual response time.

DISTRIBUTED DATABASE MANAGEMENT SYSTEMS RELIABILITY

As explained in the introduction, a potential benefit of a distributed DBMS is improved reliability: when a component of the system fails, some or all queries may still be processed, as opposed to a centralized DBMS, in which the failure of the central server leads to failure of the whole system. Of course, this benefit will be effective only if specific steps have been taken at the design level so that the system can take advantage of its inherent distribution in order to improve its reliability.

Typology of Failures in DDBMS

The failures that can occur in a DDBMS can be put into four categories (Özsu and Valduriez 1999):

- Transaction failures: abnormal termination of a transaction
- System failures: either hardware (disk, memory) or software (OS or database server) failures. This means that the parts of the database that might have been in main memory, called the “volatile database” (typically the results uncommitted operations) are lost, while the database stored on secondary storage (stable database) remains correct (though out of date).
- Media failures: a fault in secondary storage devices hosting a part of the database.
- Network failures: all problems related to the communication system. This type of failure is unique to DDBMSs with respect to centralized systems. Here we restrict ourselves to the network failures about which a DDBMS can take action as opposed to those that are the sole responsibility of the network. This means lost/undeliverable messages and line failures.

Local Reliability

One possibility to improve the reliability of a DDBMS is to use local a reliability manager (LRMs) on each DBMS comprising the system. The purpose of this component is to prevent the problems related to local system failures. As such, it is similar to its counterpart found in centralized DBMSs. This technique is based on the logging of all database operations, so that when a system failure occurs, previous operations can either be redone or undone, depending on the point of the transactions in which the failure occurred.

Media failures are another type of fatality that can be dealt with at the local level. Media failures are characterized by the fact that they cause data losses in the stable database and/or log. To counter this, the LRM can manage a backup of the database, and the log can be stored on a different secondary storage device. Many techniques have been developed for creating and maintaining such backups efficiently without affecting the performance of the stable database server (see Bhalla and Madnick 2004 for an overview).

Distributed-Reliability Protocols

The protocols relevant to reliability for DDBMSs are:

- *Commit*: the general commit procedure
- *Termination*: the action to be taken to terminate a transaction when one of the participating sites failed
- *Recovery*: how a site that failed in the middle of a distributed transaction can return to a stable state

Commit Protocols The two phase commit (2PC) (Lampson 1981) is meant to ensure the atomic commitment of distributed transactions—that is, the fact that a distributed transaction must either succeed or fail (in which case, all its proposed changes are discarded), in a context in which system failures may occur at sites.

2PC requires a central point of coordination (the coordinator) that can send sub transactions to each relevant site (the cohorts). Theoretically each site should answer to the coordinator that it will either commit or abort the transaction. Assuming that there is no site failure

(that is, that the coordinator does receive answers from each cohort in the system), there are two possibilities:

- At least one site replied with an abort message: the distributed transaction must be aborted. The coordinator sends a global-abort (rollback) message to the cohorts, which abort their subtransactions accordingly.
- All sites replied with commit. The coordinator sends a global-commit message to the cohorts, which commit their corresponding subtransactions.

In both cases, the cohorts send an acknowledgment message to the coordinator after having complied with the final decision. The 2PC protocol can be divided into a voting phase, in which cohorts “vote” for acceptance or rejection of the transaction, and a completion phase, in which the transaction is actually executed or rejected hence, the “two-phase” name.

2PC has the drawback of inducing substantial cost overhead during normal transaction execution, because of its message complexity, as it requires a large number of messages between the coordinator and the cohorts, and because of the amount of log information that the coordinator and the cohorts must maintain during the transaction. Therefore, many proposals have been made in the literature to either optimize or replace 2PC. For example, recent years have seen a renewed interest in one-phase-commit (1PC) protocols (Abdallah, Guerraoui, and Pucheral 2002). These protocols manage to have only one phase by discarding the voting phase, overlapping it with the execution of operations in the cohorts.

While improving performance over 2PC, IPC protocols and other alternative distributed commit protocols usually make strong assumptions about how cohorts execute transactions and about the organization of the distributed system. This makes them impractical in several cases, which is probably the reason why 2PC remains the most widely used protocol despite its shortcomings: 2PC has been successfully used in large-scale distributed environments since the 1980s (Samaras et al. 1993) and is a universal feature of modern DBMSs (Greenwald, Stackowiak, and Stern 2004). Hence, we will assume 2PC to be the commit protocol for the remainder of this section. This is necessary because the termination and recovery protocols, which are described in the next paragraphs, are closely dependent on the commit protocol operated in the system.

Termination Protocol The 2PC protocol being synchronous, it mandates the use of time-outs so that failures can be identified and action subsequently taken. The termination protocols define what action to take in these cases. With 2PC there are two time-out cases to consider: time-outs at the coordinator and time-outs at a cohort.

For a coordinator, the time-out can either occur when waiting for votes, in which case it globally aborts the transaction, or when waiting for the acknowledgment of a global commit or global abort. In this case the only option is to repeatedly resend the message to the failed site, since the other cohorts have already processed the transaction.

For cohorts, the main problem is that of a time-out occurring while the site has already voted “commit” and is waiting for the decision of the coordinator. Because of the logic of 2PC, the site cannot decide to abort or commit

the transaction on its own. If it can communicate only with the coordinator, it can only block indefinitely until the coordinator answers. As such it is desirable that cohorts have the possibility of communicating with one another. In this case, the site experiencing the time-out can query the other cohorts and take action depending on their responses.

Recovery Protocol The recovery protocol defines what a node of a distributed system must do when it has managed to restore itself to a stable state after experiencing a failure. For a coordinator, the main cases are the following:

- If it failed after sending an initial transaction message to the cohort, chances are it lost some answers and should therefore resend the message.
- If it failed after sending its commit or abort decision to the cohorts, it generally does not have anything to do.

For a cohort, the main cases are the following:

- If the failure occurred after the cohort received a transaction message from the coordinator but before it responded to it, it globally aborts the transaction. This is because of how coordinators handle time-outs in this case, as described in the preceding section.
- If the failure occurred after the cohort responded “abort,” or after it received a global abort message, the site can resume normal operations, since it can assume that the transaction has been globally aborted.
- If the failure occurred after the cohort voted “commit,” the cohort can treat it as a time-out and launch the termination protocol described in the previous section.

DISTRIBUTED DATABASES INTEROPERABILITY

Interoperability is a large problem, and a number of its aspects that are relevant to DDBMSs have solutions that are outside the scope of this chapter: standard network protocols allow heterogeneous operating systems to communicate, a standardized query language such as SQL allows distributed queries to be valid across different types of component databases, etc. In this section, we focus on the interoperability problems that is the most specific to DDBMSs, that of the resolution of heterogeneity at the schema level. This places us in the “multidatabases” case, as defined previously in the “architecture” section.

Schema Translation/Schema Integration

The problem of heterogeneity at the schema level can be addressed by a database integration process, the goal of which is to create a global schema of the distributed database. As previously explained, certain types of multidatabases do not necessarily need a global schema. Therefore, this process is relevant only to systems that do have one.

Database integration comprises two steps: schema translation, and schema integration.

Schema translation means transforming each component schema *I* to a common canonical representation.

This translation does not concern the semantics of the schemas, but the model in which they are expressed (such as relational, entity-relationship, object, ...).

Many techniques of schema translation from one specific data model to another have been developed. For a complete description of common cases of schema translation, see Silberschatz, Korth, and Sudarshan (2006). These techniques are widely used, though research on model-independent translation—that is, techniques that can be used for any translation regardless of the original and target model types—remains active (Atzeni, Cappellari, and Bernstein 2006).

Schema translation is followed by schema integration, which involves the following tasks:

1. Identifying the components of a database which are related to others.
2. Selecting an appropriate representation formalism for the global schema.
3. Actually integrating the initial schemas into a global conceptual schema.

Two types of approaches exist in terms of schema integration: the binary approach and the n-ary approaches (Batini, Lenzirini, and Navathe 1986).

In the binary approach, two different schemas are integrated into one at each step. This approach can either be balanced or stepwise. In balanced schema integration, schemas S_1 and S_2 are integrated into schema S'_1 , schemas S_3 and S_4 are integrated into schema S'_2 , and so on until all input schemas have been processed. The S'_i 's schemas are themselves pairwise integrated; the process is repeated until only one schema remains. A stepwise schema integration process starts by integrating two schemas. The resulting schema is then integrated with a third one, and so on until only one integrated schema remains.

With n-ary schema integration, more than two schemas are integrated at each step. The process can be either single-pass or iterative. A single-pass process integrates all schemas at once. In iterative n-ary schema integration, variable numbers of schemas are integrated at each step. There should be more than one step (otherwise the process falls into the single-pass case), and one of the steps should involve more than two schemas (otherwise it is equivalent to a binary schema integration).

Most available tools implement binary techniques, because they are easier to partly automate, while n-ary integration typically involves more complex cases. N-ary is advocated by researchers who argue that more information is available at each step, which can prevent poor intermediary decisions. To clarify matters, the next sections will assume a binary process applied to entity-relationship (ER) schemas.

Semantic Heterogeneity

A key issue in an integration process is that of the semantic heterogeneity. Although researchers do not agree on a precise definition of semantic heterogeneity, a generally accepted framework is the following: “variations in the manner in which data is specified and structured in different components” (Hammer & McLeod, 1993). Semantic heterogeneity is characterized by the existence

of semantic conflicts between schemas. Transforming one or all schema(s) to resolve these conflicts is called homogenization. This process can be followed by integration, in which the homogenized schemas are combined.

Hammer and McLeod (1993) include a detailed taxonomy of semantic heterogeneity issues. The most prominent ones are naming conflicts, which can involve either homonyms or synonyms. Homonyms are database entities that have the same name but different meanings, while synonyms have different names but the same meaning.

Homonymy issues are usually easy to address: having different meanings, homonyms only have to be differentiated and not integrated. A common solution is to prefix the entities with their site and/or original relation names.

On the contrary, there exists no systematic way to resolve synonymy. In this context, ontologies have drawn much interest from the research community in the past few years (Wache et al. 2001), and have become the preferred way to deal with synonyms.

An ontology is basically a data model that represents a domain of knowledge. Ontologies are generally defined using four basic types:

- *Individuals*: objects (or instances)
- *Classes*: types of individuals. The notion is similar to that of object-oriented programming in particular inheritance is possible
- *Attributes*: features, properties, characteristics or parameters specific to an object
- *Relations*: characterization of relationships between objects

Ontologies provide a reference naming framework specific to a domain. In the context of semantic heterogeneity between schemas, if all schemas conform to the ontology related to their domain, their entities are named consistently, and synonymy issues can be avoided. As such, ontologies are the most useful when they are used at the design stage; however, they can also help resolve semantic heterogeneity between “ordinary” (non-ontology-based) schemas by providing a point of reference to which the entities of the schemas can be manually translated.

The problem of ontologies is that they are useful only if all experts of their domain agree on their content, a consensus that is generally hard to achieve. A typical example of this can be found in this very text: as noted above, experts do not agree on the exact definition of “semantic heterogeneity”!

Another source of semantic heterogeneity is the problem of structural conflicts between schemas. Four types of structural conflicts exist:

1. *Type conflicts*: for instance an attribute in one schema being modeled as an entity in another
2. *Dependency conflict*: identical relationships having different cardinalities
3. *Key conflicts*: identical relationships with different sets of candidate keys or primary keys
4. *Behavioral conflicts*: conflicts related to triggers, integrity constraints and other similar mechanisms

Methods of solving structural conflicts differ, depending on the data model in which the schemas are expressed (see, for example, Yang, Lee, and Ling 2003) for XML schemas). However, the idea is generally to transform entities, relationships, and attributes into one another. This generally requires human intervention to take the semantics of the schemas into account.

Homogenization of two schemas can be performed only once the relationships between them have been precisely determined. There are four possible types of relationships between schemas:

1. *Identity*: To each element of one schema corresponds one and only one element in the other schema.
2. *Inclusion*: One schema is a subset of the other.
3. *Overlapping*: Some elements of one schema are found in the other, but both have unique elements.
4. *Empty intersection*: The schemas are strictly disjoint.

As with many other parts of the homogenization process, identifying the relationship between two schemas requires human intervention, as the semantics of the schemas must be understood.

After homogenization, the actual integration into a single schema can be performed. This integration is fairly straightforward once all the issues described above have been resolved. Three dimensions have been identified in order to measure the quality of the outcome of an integration process (Batini et al. 1986):

1. *Completeness*: The whole semantics of the input schemas is retained in the global conceptual schema.
2. *Minimality*: The resulting schema should contain no redundant entity.
3. *Understandability*: The final schema should be easy to understand for a reasonably qualified observer. This should ideally be the main criterion of quality of a GCS; however, it is difficult to evaluate precisely because of its subjective nature.

DATAGRIDS

Datagrid Basics

Grid computing is an emerging computing model that was first formally introduced in 1998 by Foster and Kesselman (see *Grid Computing Fundamentals* and *Grid Computing Implementation* for more details on Grid computing). A Grid is a middleware system that takes advantage of the capabilities of a large number of heterogeneous interconnected computers in order to execute high performance computing applications. Typical Grid applications include scientific applications (high-energy physics, biology, meteorology, etc.) and business-oriented applications (complex financial modeling, highly distributed engineering projects, etc.).

The original “Grid book” (Foster and Kesselman 1998) defined a computational Grid as “a hardware and software infrastructure that provides dependable, consistent, pervasive, and inexpensive access to high-end computational capabilities.” This definition insisted on the sharing of the computing power of a large number of internet-

worked devices. However, many computer scientists who followed up on the idea argued for a broader definition encompassing the sharing of resources in general, especially including storage resources and data. This prompted the development of Grid systems mainly concerned about data sharing as opposed to computing power sharing called datagrids (Rajasekar et al. 2003). By allowing the sharing of large data sets distributed across a large number of computer facilities and multiple administrative domains (called virtual organizations in Grid context), the Grid paradigm is a means through which the promises of DDBMSs as defined in the introduction of this chapter can be fulfilled (Stockinger 2001). Ddatagrids even go beyond these promises, since their “resource-sharing” philosophy allows the integration not only of structured data stored in DBMSs but also of unstructured data found in other data sources (file systems, directories, archives...).

Grid technology is a work in progress, with many practical issues still within the realm of research; however, commercial applications have started to appear. This trend is outlined by the fact that major DBMS vendors have introduced Grid facilities in the latest versions of their software.

Another important development in the Grid community is the introduction of Grid standards. With the large number of Grid projects springing up in the beginning of the 2000s, the need for Grid standards has quickly become obvious. This led to the foundation of the Global Grid Forum (GGF, www.gridforum.org), which issues standards for various aspects of Grid technology after extensive discussion in the community. Another major player in the Grid world is the Globus project (www.globus.org), which developed a toolkit that has become a de facto standard for Grid systems and applications development, implementing some of the GGF standards.

One very important trend in the latest Grid standards is their growing integration with Web services standards, in particular through the definition of the open Grid services architecture (OGSA, <http://globus.org/ogsa>). OGSA defines a service-oriented architecture through a set of core functionalities, including authentication, service discovery, service monitoring, etc. OGSA capabilities can be implemented as Web services with the Web Service Resource Framework (WSRF, www.globus.org/wsrf) specification.

General Grid Data Management Techniques

Ddatagrids need the following data management capabilities (Moore et al. 2004):

- Data-transfer mechanisms between nodes
- Replication mechanisms
- Metadata support
- Information repository abstraction for accessing multiple databases

Additional mechanisms are, of course, required for typical Grid system functioning (security, service-management capabilities, services related to distributed job execution, etc.).

but will not be detailed here, as they are not specific to data management.

Data Transfer

Grid data management requires efficient data-transfer services over wide area networks. A typical Grid transfer service is *GridFTP* from Globus, which defines a file transfer protocol (FTP)-like protocol with extensions taking advantage of the grid's characteristics: parallel transfers, partial transfers, reusable transfer channels. Globus also provides the reliable file transfer (RFT) service, a WSRF service that basically adds high fault tolerance to a GridFTP-like service.

Replica Management

Replication is a key technique for the design of efficient datagrids, as it can dramatically improve their performance: no matter how fast the network, strategically placed replica will always have a significant impact on query processing and retrieval times. Liberal replication also provides an additional level of fault tolerance: when a resource is unavailable, the data can still be accessed through its replicas.

Replication requires mechanisms for the definition of logical file names (LFNs), which are identifiers of a file replicated across the system. All replicas of a specific file share the same LFN. LFNs are opposed to physical file names (PFNs), which uniquely identify each file available in the Grid. A PFN is typically composed of the concatenation of the address of a storage resource with an LFN.

In this context, datagrids usually provide two replica management services: a replicator, which uses Grid data-transfer services to create copies of specified data at a specified location; and a replica location service (RLS), which can be queried to find the replicas of a given LFN. When creating replicas, the replicator registers them with the RLS. With current datagrids, replication is generally initiated by users; however, the transparency philosophy of the Grid should lead to the development of automatic replication by the middleware.

Metadata-Related Functions

Datagrids provide access to very large data sets. Many of these are described using metadata, implemented as a set of fields attached to data objects. Because the purpose of early datagrids was often to let members of a scientific community access large data resources relevant to their domain, the need for metadata integration arose quickly. This was usually performed with metadata catalogs. Grid metadata integration also first outlined the need for database integration into datagrids, as users needed to issue complex queries on metadata in order to discover interesting data.

Metadata can generally be divided into two categories: domain-related metadata (information relevant to only the members of a community), and domain-independent metadata (e.g. data size, owner, etc.). Ontologies are often used in order to define a naming space in which such information can be expressed consistently.

An example of a Grid metadata service is the Metadata Catalog Service (MCS) (Deelman et al. 2004), a Globus application built on top of OGSA-DAI (see below). Metadata related to files or collections of files are stored in a database. MCS provides a query interface to this database. For file-related metadata, the result of a query is a set of logical file names, which can be sent to the RLS to locate them. Metadata attributes can also be dynamically added by users.

Database Access

Early Grid applications were concerned mainly with the processing of scientific data, often stored as collections of files. As Grid application domains broadened over time, the need for the support of more structured data such as DBMSs repositories became quickly obvious.

This prompted much research in the field, mainly in two directions: providing a standard interface with which databases can be accessed through the Grid middleware, and defining an infrastructure using Grid resources in order to evaluate and execute distributed queries on grid-accessible DBMSs. This materialized with the *OGSA-DAI* (OGSA database access and integration [Antonioletti et al. 2005]) and *OGSA-DQP* (OGSA distributed query processing [Alpdemir et al. 2003]) projects.

The main goal of OGSA-DAI is to provide a common interface to various types of data resources available on a datagrid. Its architecture comprises three types of services: Service Consumers, GDSF/GDS (Grid data service factories/Grid data services), DAISGR (DAI Service Group Registries). Service consumers are services trying to discover available data and to perform queries on them. A GDS service provides a data source abstraction, which allows access to data through consistent interfaces, regardless of their specific format. This is achieved thanks to plug-ins developed for each supported data-source type. There are plug-ins for all major DBMSs. A GDSF is responsible for creating a GDS when source appears and for publishing its availability to DAISGR services. The DAISGR services thus represent a directory of available data resources, which can be queried by service consumers.

OGSA-DQP is a framework for defining distributed query processors that can execute queries over data wrapped by OGSA-DAI. In accordance with the transparency philosophy of the Grid, the "orchestration" of the queries is left to the processor, which can have DQP services compile, optimize, and schedule queries. OGSA-DQP queries are written in object query language (OQL; Cattell et al. 2000). Client applications may use a translation service to translate queries into OQL. A query is separated into a number of partitions, each of which encapsulates the role of an individual service in the query evaluation and corresponds to a query execution plan. Queries are sent to a "query statement activity" service. This service parses queries, divides them into partitions, optimizes them, schedules them, and sends each partition to DQP evaluator services. These services can evaluate and execute a query plan provided as an input, and communicate with other evaluators for synchronization. These evaluators are included in "DQP resource," which

encapsulate a distributed query management execution architecture: DQP evaluator, OGSA-DAI data services, etc. A DQP factor activity enables the creation and configuration of these resources so that a new infrastructure can easily be added.

SUMMARY

In this chapter, we have defined distributed database systems and presented the related issues with their usual state-of-the-art solutions: the choice of an architecture, the main options being client/server, peer-to-peer, and multidatabase; the design methods, especially in terms of fragmentation and fragment allocation; distributed query processing, dealing with how execution plans are computed and queries are optimized; DDBS reliability issues, especially how transactions can be committed in cases of site failures; and DDBS interoperability, notably the resolution of semantic heterogeneity issues when a global conceptual schema of the whole distributed database is wanted.

Distributed databases have been around for a long time. They represent a well-tested technology used daily by many large organizations. Despite this, research remains active in the field. One first type of research deals with specific issues of DDBMSs for which an optimal solution is not available (such as a number of NP-complete problems that were identified in this chapter). Perhaps most notably, the second type of research works results in introducing distributed databases in contexts in which they had not been used before:

- Peer-to-peer technologies allow a DDBMS to be built by aggregating to build the information carried by a very large number of lightweight clients.
- The Grid paradigm puts more power in the middleware, opening opportunities for an easier construction of DDBMSs, integrating various heterogeneous data sources.

Indeed, these new applications are characterized by the large number and heterogeneity of the data they integrate, as opposed to the handful of database servers comprising traditional distributed systems; hence the activity in the research related to semantic heterogeneity, upon which the success of this new breed of DDBMSs largely depends.

GLOSSARY

Component Database: Database participating in a distributed database system.

Datagrid: Middleware system taking advantage of a large number of interconnected computing resources with a focus on using them for data management purposes.

Fragmentation: Partitioning of a relation into subrelations to be distributed across the participating sites of a DDBMS. Horizontal fragmentation partitions relations into subsets of tuples, while vertical fragmentation divides them according to subsets of their attributes.

Global Conceptual Schema: Database schema encompassing a whole DDBMS even if it comprises component

databases initially defined through their own independent schemas.

Localization: In the context of DDBMSs, localization is the process through which a distributed query expressed on global relations is translated to a query expressed on fragments.

Multidatabase: Distributed database management system built out of several existing databases.

Schema Integration: Process through which the schemas of several databases are combined into a single schema, that usually involves the resolution of semantic conflicts between the schemas to be combined.

Schema Translation: Process through which a database schema is transformed from a formalism of representation to another, with a view to a future integration with other schemas.

Semijoin: Relational operator that selects the tuples of a relation that participate in the natural join of this relation with another one. Semijoin operators are widely used by distributed query optimizers.

Transparency: Key feature of DDBMSs that allows users to interact with the system as if it were a single centralized DBMS, unaware of the geographical location and distribution of the data.

Two-Phase Commit Protocol: Distributed algorithm that ensures that all nodes of a DDBMS globally commit or globally abort a distributed transaction even in cases of failure of one or more participating node(s).

INTRODUCTION

Network capacity planning is the process of determining the resources that will be needed for a network to support the network traffic that is offered to it. Capacity planning is challenging because network capacity is affected by many factors, including the bandwidth of network links, the capabilities of network servers, and the performance of internetworking devices. Capacity planning is also difficult because it involves predicting the future. To accurately provision capacity, network engineers must try to learn what users are doing now, what they will be doing in the near future, and what they will be doing in a few years.

Despite the difficulties, capacity planning is one of the most important tasks an engineer will take on. Without enough capacity, a network experiences unwanted delay and errors, especially as load increases. Too much capacity wastes money and can result in problems in other parts of the network that cannot handle the extra traffic. The right amount of capacity, on the other hand, helps engineers meet current and future needs, achieve service-level objectives, minimize risks associated with unexpected traffic surges, and proactively identify bottlenecks. With a good plan, bottlenecks can be placed where they will cause the least disruption to the network, and internetworking devices can be configured to accurately prioritize traffic when there are bottlenecks.

This chapter presents capacity-planning terminology and principles, as well as recommendations for capacity planning processes. Capacity planning processes include gathering information about requirements, analyzing potential solutions, reviewing constraints and trade-offs, testing solutions, and gathering requirements information again. Capacity planning is not a linear step-by-step process. Rather, it is a creative, recursive process, in which multiple solutions are envisioned and evaluated. This chapter suggests possible ingredients for a good solution, but leaves it up to the reader to creatively select the right solutions based on actual requirements and constraints.

CAPACITY-PLANNING TERMINOLOGY

Planning is the act of designing a realization of a goal. Capacity planning involves designing the capacity that

will be required of a network to meet the business and operational goals of the network users. Network capacity can be expressed in terms of network link bandwidth, network architecture and performance, server architecture and performance, router architecture and performance, application behavior, and so on. This section expands on these basic principles and defines capacity.

Definitions of Capacity

Capacity refers to the potential or suitability for holding, storing, or accommodating something. For example, the capacity of a bucket could be one gallon or the capacity of an auditorium could be 100 people. Networks hold (and convey) network traffic caused by network applications, such as Web browsing, file sharing, music downloading, video streaming, and searching for extraterrestrial intelligence (SETI). Network capacity is the potential for a network to accommodate the network traffic that is presented to it by network applications.

Sometimes the word *capacity* refers to the facility to produce something, such as the production capacity of a factory or the power-producing capacity of a generator. Networks do not really produce anything. Nonetheless, a network—and the networking devices that comprise it—does receive inputs and generate outputs (in the form of packets), and the rate at which it can do this has a major affect on network capacity.

Shannon's law, developed by Claude Shannon, a mathematician who helped build the foundations for modern computers, expresses capacity in terms of the maximum bits per second that a channel can carry in the presence of electrical noise. Shannon's law states that the highest obtainable error-free data rate, expressed in bits per second, is a function of the bandwidth (in Hertz) of the channel and the signal-to-noise ratio.

The broad concept to understand with Shannon's law is that raw frequency is not the only ingredient of capacity. Electrical noise affects capacity. To carry that concept a step further, it is also important to realize that capacity, as measured in raw bits per second, is not the only ingredient of network capacity. Network capacity is affected by network topologies, link characteristics, servers, routers, switches, firewalls, operating systems, and applications.

One final note with regard to definitions: Capacity should be distinguished from throughput. Throughput

is a measure of how much actual traffic can be passed across a network path in a stated period of time (whereas capacity is the potential for a network to accommodate network traffic). *Throughput* usually refers to user data and is lower than capacity because it is affected by network congestion, server congestion, framing overhead, packet overhead, background traffic, and errors.

Network Capacity

In summary, the capacity of a network is provided by the following:

- The network topology
- The bandwidth (data rate in Mbps or Gbps) of local area network (LAN) links
- The bandwidth of wide area network (WAN) links
- The bandwidth of metropolitan area network (MAN) links
- The bandwidth, storage capacity, and disk access speed of storage area networks (SANs)
- The features of network servers, including CPU power, the amount of random access memory (RAM) and disk storage, RAM and storage access speed, bus speed, and operating system and application software behavior
- The features of internetworking devices (routers, bridges, switches, firewalls, wireless access points, concentrators, multiplexers, content switches, and load balancers), including CPU power, the amount of RAM and disk storage, RAM and storage access speed, bus speed, operating system and application software behavior, and packets-per-second (PPS) forwarding rate.

CAPACITY-PLANNING PROCESS

Capacity planning should be a structured, analytical process based on engineering design principles. Capacity planning requires gathering information about business and operational goals, applications, the current network's infrastructure and performance, and network traffic. After information is gathered, potential solutions should be developed and tested. Finally, a solution that is based on analysis and testing, and that is also flexible and modular so that changing needs can be met, should be selected and implemented. After the solution is implemented, it should be continually monitored to determine whether it is still working and meeting user needs. The job of a network engineer is never finished. Figure 1 illustrates the capacity-planning process discussed in this section.

Gathering Information

The first step for most planning projects is to gather information. Determining how much capacity a network will need requires gathering information about business drivers, applications, the current network, and traffic classes and patterns. These details are inputs to the capacity-planning process. A plan for a network with sufficient capacity is the output of the capacity-planning process.

Figure 1: A capacity-planning process

Figure 2 shows the inputs and outputs of a capacity-planning process.

Business Drivers

Computer networks exist because they solve a business or operational problem. Network upgrades are made not because some new technology sounds cool to the network engineers, but because they help an organization achieve its goals, whether the goals are to increase profits, gain market share, improve worker productivity, streamline processes, or something else unique to the organization. An important aspect of capacity planning is an analysis of the business or operational goals of the network. Likewise, an important aspect of a capacity-planning project is an analysis of the specific business or operational goals of the project. As part of this analysis, the engineer should gain an understanding of the scope of the capacity-planning project. Is the project related to a single network link, a set of LANs, a set of WANs or remote-access networks, or the entire internetwork?

Applications

Computer networks carry application data. While gathering information for a capacity plan, an engineer should identify user applications. Later, the engineer can characterize the applications' capacity requirements, as covered later in this chapter in the section on "Analyzing Network Traffic Patterns," but at this point, the engineer should

Figure 2: Inputs and outputs of a capacity-planning process

simply identify the major applications that offer traffic to the network, including e-mail, file-oriented applications, database access and updating, Web browsing, remote terminals, voice, video, network games, and so on. The above list is for user applications, but the capacity of the network must also support network services such as dynamic addressing, naming and name resolution, user authentication and authorization, remote booting, directory services, network backup, network management, software distribution, and so on.

Current Network Structure

An effective capacity-planning process starts with a characterization of the architecture of the current network. Engineers should learn the location of major network links, servers, server farms, and internetworking devices, and develop a set of detailed maps. If accurate maps already exist, they can be used, but often network documentation is out of date and should not be trusted without additional investigation.

While documenting the network structure, it is a good idea to take a step back from the detailed diagrams and try to characterize the logical topology of the network as well as its physical components. The logical topology depicts the overall design of a network; it can affect the upgrade of a network. For example, a flat topology, with no modularity or hierarchy, is hard to upgrade. A modular design, on the other hand, allows parts of a network to be upgraded without affecting the entire network.

Current Network Performance

Before engineers can decide how much additional capacity is needed for a network, they need to know how much it currently has, how much of that current amount is actually being used, and how well the network is performing with its current capacity. A baseline measure of the current performance of a network is an important input into the capacity-planning process. This measure should include information about bandwidth utilization, efficiency, availability, accuracy, response time and delay, and the status of major internetworking devices. (Oppenheimer 2004).

Bandwidth utilization is a measure of how much bandwidth is in use during a given time interval, usually specified as a percentage of the maximum theoretical bandwidth. For example, a measuring tool might specify that traffic is using 70 Mbps on a 100-Mbps Ethernet link—in other words, 70%. (Some tools might call this 35% of a full-duplex Ethernet link.)

Network monitoring tools use different time intervals for computing bandwidth utilization. Some tools let the user change the interval. Using a long interval (such as an hour or longer) can be useful for reducing the amount of data that the tool outputs, but granularity is sacrificed. Peaks in network traffic get averaged out. Using a time interval of a few minutes is a better plan, so that short-term peaks can be factored into the capacity-planning process. If practical, monitoring tools should run for at least a few days. If the project goals include improving performance during the busiest times, utilization should be measured during these times, not just on typical days. For example, an online store should measure utilization during the Christmas-shopping season.

Sometimes bandwidth is used inefficiently. One aspect of capacity planning is to determine whether there are any optimizations that can be done so that bandwidth is not wasted. Bandwidth utilization is optimized for efficiency when applications and protocols are configured to send large amounts of data per packet, thus minimizing the number of packets and round-trip delays required for a transaction. The number of packets needed for each transaction can also be minimized if the receiver is configured with a large receive window, allowing it to accept multiple packets before it must send an acknowledgment. The goal is to maximize the number of application-layer data bytes compared to the number of bytes in headers, acknowledgments, and other overhead information. (Note that an exception to this is networks with voice traffic and slow links. Voice uses small packets and works best when other applications also use small packets, so that the transmission time for outputting large packets does not cause extra delay for the voice applications. This is especially true for slow links.)

The availability of the network can be specified as a mean time between failures (MTBF) and a mean time

to repair (MTTR). A baseline analysis of the current network should also include information about the accuracy of the network in terms of bit-error rates on WAN links, cyclic redundancy check (CRC) errors on LAN links, and dropped packets. If bandwidth is being wasted by re-transmissions due to errors and dropped packets, these problems should be fixed, if possible, before more capacity is provided.

It is important to measure response time before and after a new capacity plan is implemented. Response time can be measured from a user's point of view by running representative applications on a user's workstation and measuring how long it takes to get a response. The time it takes to retrieve e-mail, send a file to a server, download a Web page, update a sales order, print a report, and so on, can be measured. In addition, the response time for network services should be measured. This includes measuring the time it takes to get an answer to a domain name system (DNS) query, a dynamic host configuration protocol (DHCP) request for an Internet protocol (IP) address, a user authentication request, and so on.

Another way to estimate response time and delay in a network is to send ping packets and measure the average round-trip time (RTT) to send a request and receive a response. Deviation from the average RTT can also be measured, which is important for applications that cannot tolerate jitter, such as voice and video. (*Jitter* in this context means a measure of the variability over time of the average delay across a network.)

The final step in analyzing the performance of the current network is to check the status of the servers and internetworking devices in the internetwork. It is not necessary to check every LAN switch, but the major switches, routers, firewalls, and servers should be checked. Checking the status includes determining how busy the device is (CPU utilization), how many packets it can process in a given time, how many packets it has dropped, and how efficiently it is using, creating, and deleting memory buffers. Checking utilization of storage and RAM is also important on some devices.

Analyzing Network Traffic Patterns

As mentioned above, network capacity can be defined as the potential for a network to accommodate the network traffic that is presented to it. To plan how much capacity is needed, the traffic must be understood. Both current and future traffic should be classified and studied so that capacity planning can be based on traffic behavior, flow, and load.

Network Traffic Classes

A broad categorization of network traffic is background versus transactional. Background traffic is a by-product of the protocols that are used on networks. For example, in a Windows environment, when a user maps a drive to a network share, the server message block (SMB) keep-alive packets between the PC and server are background traffic. Transactional traffic is generated when a user performs a task. For example, when a bank teller enters a deposit for a customer, transactional traffic is generated (Baron 2005).

SMB is one of many protocols that send keepalives. Several voice-over-IP (VoIP) implementations send constant keepalives as a way of making sure that a session is available when it becomes necessary to ring the phone. Background traffic other than keepalives includes address resolution protocol (ARP) traffic, routing table updates, bridge protocol data units (BPDUs) sent by bridges and switches, and network management traffic. Network services background traffic associated with DNS, DHCP, user authentication, directory services, and so on must also be accommodated by a capacity plan.

Another categorization of network traffic is broadcast versus unicast. Broadcast traffic goes to all devices in the broadcast domain. It does not necessarily use more bandwidth than unicast traffic. (Broadcast packets are often smaller and less frequent than unicast packets.) However, broadcast traffic does disturb every station in the broadcast domain, which reduces the processing capacity that is available for other traffic, which is especially a problem for low-end devices. Broadcast domains should be limited in size, which can be accomplished with routers and virtual LANs (VLANs).

Network traffic can also be characterized with regard to the quality of service (QoS) that it requires. For example, the traffic might be especially sensitive to dropped packets, as in a bank transaction; or the traffic might be especially sensitive to delay, as in voice and video traffic; or the traffic might need high throughput, as in a file-upload application.

Some traffic requires a controlled-load service, as defined in RFC 2211 (Wroclawski 1997). With controlled-load service, the network provides a service that closely approximates the service that the traffic would receive on an unloaded network. The network is expected to apply admission control to ensure that the sensitive traffic receives the service it needs, even when the network is overloaded. An application that requests controlled-load service assumes that a very high percentage of transmitted packets are delivered and the transit delay by a very high percentage of traffic does not greatly exceed the minimum transit delay experienced by any successfully delivered packet. The controlled-load service is intended for applications that are highly sensitive to overload conditions. Important members of this class are "adaptive real-time applications" (Wroclawski 1997).

Some real-time applications are not adaptive and have stricter requirements with regard to delay and dropped packets than the controlled-load service can offer. The guaranteed service defined by RFC 2212 (Shenker, Partridge, and Guerin 1997) provides firm bounds on end-to-end packet-queuing delays. Guaranteed service is intended for applications that need a guarantee that a packet will arrive no later than a certain time after it was transmitted. With this service, the maximum queuing delay can be mathematically proven to be at a certain level. The guaranteed service does not attempt to minimize jitter. It is also not concerned with fixed delay, such as propagation delay across a network path, since there is not much it can do about the speed of light. Instead, guaranteed service guarantees that packets arrive within a guaranteed delivery time and that they are not discarded due to queue overflows.

According to RFC 2475 (Blake et al. 1998), IP packets can be marked with a differentiated services codepoint (DSCP) to influence queuing and packet-dropping decisions on an output interface of a router. The DSCP can have one of sixty-four possible values that specify how each router should handle the packet. Packets can be marked in such a way that a properly configured router implements controlled-load service, guaranteed services, and other QoS functionality. When conducting research for a capacity plan, if a network engineer discovers applications that are sensitive to delay and load, the plan must specify a need to deploy routers that support QoS features.

Network Traffic Behavior

Using a protocol analyzer and network modeling tools, an engineer can learn how network applications and protocols behave and use this information to plan capacity. How many and what types of packets do the applications and protocols send? How big are the packets? How quickly are the packets sent, and if not acknowledged, how quickly are they resent? Are the packets sent in bursts? Do the packets include lots of overhead?

As mentioned above, capacity planning should take into account network traffic that has not (or cannot be) optimized for packet-size efficiency. When network applications send small packets, a lot of capacity is consumed by packet headers. When possible, applications should be tuned to use large packets. Another contributor to capacity-usage inefficiency is applications that send numerous acknowledgments (acks), sometimes at multiple layers. For example, some implementations of Windows file sharing send acks at the SMB, NetBIOS, and transmission control protocol (TCP) layers. This may not be avoidable, but it is worth knowing about, as it affects capacity usage.

In some cases, capacity-usage inefficiencies can be avoided through the use of TCP extensions. For example, RFC 1323 (Jacobson, Braden, and Borman 1992) provides a method for scaling the TCP receive window beyond the maximum size that the 16-bit window size field in the TCP header nominally allows. As another example, RFC 2018 (Mathis et al. 1996) helps reduce capacity usage by optimizing error recovery and retransmission behavior.

Without RFC 2018, TCP acks are cumulative up to the point at which a problem occurs. If TCP segments are lost, the ACK number is one more than the number of the last byte that was received before the loss, even if more segments arrived after the loss. In other words, there is no way for a receiver to report a hole in the received data. This causes the sender to either wait a round-trip time to find out about each lost segment, or to unnecessarily retransmit segments that the recipient may have received correctly. With selective ACK, the TCP recipient fills in the selective ack option field in the TCP header to inform the sender of the noncontiguous blocks of data that have been received. The sender can then retransmit only the missing segments.

A protocol analyzer can help an engineer determine whether selective ACK is in use. A protocol analyzer can also be used to study other aspects of traffic behavior,

including packet sizes, excessive overhead traffic, windowing and flow control, error-recovery mechanisms, broadcast rates, and so on. This information can be input into the capacity-planning process to ensure that solutions are selected that accommodate this traffic behavior (if the behavior cannot be changed to be more optimal.)

Network Traffic Flow

Accurately provisioning network capacity requires an analysis of traffic flow. An identification of the major sources and destinations of network traffic, and an analysis of the direction and volume of data traveling between them, helps the engineer comprehend traffic flow and correctly provision capacity.

To get a better understanding of traffic flow, network engineers should start with an analysis of the location and network-usage habits of user communities. A user community is a set of workers who use a particular application or set of applications. A user community could be a corporate department or a set of departments. However, in many organizations, application usage crosses departmental boundaries. It is generally more effective to characterize user communities by application and protocol usage, rather than by departmental boundary. User communities should be identified and located, and their applications should be analyzed for network traffic behavior and flow.

In addition to documenting user communities, characterizing traffic flow requires locating major data sources and sinks. A data source is a device, or group of devices, that mostly produces data. A data sink (sometimes called a “data store”) is a device that mostly accepts data, acting as a data repository (McCabe 2003). Examples of data sources are devices that do a lot of computing, such as servers, mainframes, and computing clusters. Other examples, such as cameras, video-production equipment, and application servers, do not necessarily do a lot of computing, but can generate a lot of data. Data sinks include disks, tape backup units, SANs, and video-editing devices.

Analyzing traffic flow involves identifying and characterizing traffic flows between sources and sinks. In some cases, a traffic flow can be characterized as bidirectional and symmetric. Both ends of the flow send traffic at about the same rate. In other cases, a flow is bidirectional and asymmetric. Client stations send small queries and servers send large streams of data, for example. In a broadcast application, the flow is unidirectional and asymmetric. Figure 3 shows the differences between bidirectional, unidirectional, symmetric, and asymmetric traffic flows.

Network applications tend to fall into broad categories that can be characterized in terms of traffic flow. When conducting a capacity-planning project, a network engineer can categorize applications as being one of the following types: terminal/host, client/server, peer-to-peer, server/server, distributed computing, or broadcast. Once a high-level characterization is completed, a more detailed analysis of applications and their network traffic characteristics can be conducted using protocol analyzers and traffic modeling tools, but as a first step, Table 1 can be used to classify typical network application types.

Figure 3. Traffic-flow examples

Network Traffic Load

After traffic flows between sources and destinations have been identified, their size needs to be measured or predicted, using protocol analyzers and traffic-modeling tools. In other words, the engineer has to analyze the volume of network traffic caused by traffic flows and how much of a load they will put on the network. Traffic load estimates are unlikely to be precise, but they can be reasonably accurate if they are based on an analysis of measured traffic and an extrapolation from the measurements for future requirements.

Protocol analyzers and modeling tools can be used to study the traffic load caused by a single user of an application. After the load caused by a single user is analyzed, the load can be scaled by the number of users of the application to get a better idea of capacity needs for the application. The analysis of the location and size of user communities, and the identification of data sources and sinks, can help make these calculations more accurate. Traffic-modeling tools can be used to automate the analyzing of traffic load.

Developing Potential Solutions

After engineers have analyzed business and operational goals, and gathered information about network traffic patterns (including traffic classes, behavior, flow, and load), they can start selecting capacity solutions. This section discusses options for network topology design, and LAN, WAN, MAN, and internetworking device capacity.

Network Topologies

Network topology is the arrangement of nodes and links in a network. A network's topology depicts the interconnectivity of major LAN and WAN segments, internetworking devices, servers, and user communities. Once the steps of analyzing traffic flow and load are completed, a network engineer can design a network topology that

Table 1: Types of Network Applications and Their Traffic Characteristics

Type	Flow	Symmetry	Comments	Examples
Terminal/host	Bidirectional	Asymmetric	Terminal sends just a few characters	Telnet, Secure Shell
Client/server	Bidirectional	Asymmetric	Clients send queries, servers send replies and bulk data	Web browsing, e-mail, SMB, network file system (NFS), file transfer protocol (FTP), voice call setup
Peer-to-peer	Bidirectional	Symmetric	Participants may put a large load on network	Small LANs in which every computer is a server, music and video sharing, real-time protocol for voice
Server/server	Bidirectional	Symmetric	Participants may put a large load on network	Network management, directory services, caching, backup
Distributed computing	Bidirectional	Asymmetric	Task manager tells computing nodes what to do	Graphics rendering, simulations, SETI@home
Broadcast	Unidirectional	Asymmetric	The flow of broadcasts can be contained through the use of routers and VLANs	Service announcement, service discovery, address resolution

connects the right devices and sites, and offers sufficient capacity, redundancy, and load balancing.

With complex networks, in which capacity planning is approached with some care, network engineers seek to design topologies that are modular so that parts of a network can be upgraded when needed without disrupting traffic flow on other parts of the network. Network solutions can be selected on a per-module basis, with obvious distinctions being made for different parts of the internetwork. These parts may include access networks in which users reside, server networks, e-commerce networks, network-management modules, campus backbones, remote-access networks, WANs, and so on. Modular network design helps minimize costs. A network engineer can purchase the appropriate internetworking devices for each module, thus avoiding spending money on unnecessary features. Modular design also makes testing easier, because there is clear and distinct functionality for each module.

One of the best modular architectures is one that is built in a hierarchical topology that caters to flexible communications and can be replaced in layers over time (Spohn 1997). Hierarchical networks evolved from early telephone networks that were once designed in a mesh, star, or multiple-star topology. Hierarchical networks brought order out of chaos and reduced the inputs and outputs on switches, permitting the handling of high traffic on certain routes where necessary, and allowing overflow and a means of recovery from problems (Freeman 1996).

With a hierarchical topology, instead of connecting numerous devices to each other in a mesh topology, or connecting all devices to a center device in a star topology, devices are connected in a layered tree structure. Devices and links closest to the root of the tree are provided with more capacity. Traffic between layers is forwarded toward the root, although optional routes are also possible for handling overflow and recovery from broken paths. Figure 4 shows the differences between a star, mesh, and hierarchical topology.

LAN Bandwidth

The amount of LAN bandwidth provided to clients and servers plays a major role in network capacity. This section mentions the typical options that are available for planning LAN capacity, starting with the least capable and moving to the most capable wired technologies, and then covering wireless options.

Half-duplex 10-Mbps Ethernet, using a hub or legacy bus topology, is obsolete and should not be recommended for a new network design, but it still exists in some networks and should be considered in an overall capacity plan if it will not get upgraded for monetary or other reasons. Full-duplex Ethernet uses a switch and allows the connected computer and the switch port to send at the same time. Full duplex is standard these days and should be recommended. Servers, especially, benefit from full duplex because they need the ability to send a response to a client while receiving another client request. 10-Mbps full-duplex Ethernet is possible but 100-Mbps full-duplex Ethernet is the better option.

Many computers are starting to support 1000-Mbps Ethernet (Gigabit Ethernet). Although most client

Figure 4. Network topologies

computers do not need that much bandwidth yet, they will in the future, and many servers already do. 10-Gbps Ethernet is another option for servers, though it is rarely recommended for clients. As of this writing, 10-Gbps Ethernet uses only fiber-optic cabling, so it has not yet gained widespread popularity, though that will change.

Another option for servers (and the switch ports to which they attach) is Ethernet link aggregation. Link aggregation allows several Ethernet adapters to be aggregated to form a single Ethernet interface. A server that supports link aggregation considers the aggregated adapters to be one adapter and assigns one Internet protocol (IP) and one media access control (MAC) address to them, so they are treated by remote systems as one adapter. Link aggregation is standardized by the IEEE 802.3ad (IEEE P802.3ad Link Aggregation Task Force 2000) document and supported by many vendors, including Cisco Systems with its EtherChannel switch option.

The main benefit of link aggregation is that a server and switch can use the network bandwidth of all the connected adapters as one large pipe. So a single pipe could provide 800 Mbps, for example, if four full-duplex 100-Mbps adapters were linked. Another benefit of link aggregation is that capacity is still available when failures occur. If one adapter fails, network traffic is automatically sent to the next available adapter without disruption of user traffic. The capacity of the pipe is reduced but not eliminated.

The previous paragraphs discussed wired LAN technologies. Another option for users who need mobility is wireless connectivity. Wireless LANs (WLANs) do not offer as much bandwidth as wired LANs and should not be recommended unless the need for mobility outweighs the need for bandwidth. The amount of bandwidth available to a user depends on how many users are on the

wireless network (it is a shared network), as well as how far away the user is from the wireless access point and antennas. Wireless bandwidth is reduced by environmental obstacles, such as steel girders, shelving units, and metal doors that cause signal reflection. The bandwidth is also reduced if the signal is absorbed by objects with high water content, including trees, wooden structures, and even people! Nonetheless, wireless options are appropriate for environments where users roam (conference rooms, cafeterias, lobbies) and where users deploy handheld units, such as on factory floors or in retail stores.

The IEEE 802.11 Working Group has standardized the following WLAN options:

- IEEE 802.11 supports 1 to 2 Mbps.
- IEEE 802.11a supports 54 Mbps.
- IEEE 802.11b supports 1, 2, 5.5, and 11 Mbps.
- IEEE 802.11g supports 54 Mbps and is backward-compatible with 802.11b.
- IEEE 802.11n (expected to be ratified in 2008) supports up to 540 Mbps, depending on the configuration.

Today, most WLANs use 802.11g but 802.11n is expected to catch on, as it will work across longer distances than the older standards and potentially support very high data throughput.

WAN Bandwidth

When connecting sites that are geographically dispersed, typical options include leased-line and frame relay circuits, using copper cabling, and leased-line, frame relay, and asynchronous transfer mode (ATM) circuits, using fiber-optic cabling. Wireless WAN solutions may also catch on, as service providers scramble to offer new options to cost-conscious users and users who cannot be reached by cables. Wireless WANs use satellite, cellular, microwave, or radio frequency (RF) technologies.

WAN bandwidth for copper cabling is specified in North America and other parts of the world using the North American Digital Hierarchy, which is shown in Table 2. A channel in the hierarchy is called a “digital stream” (DS). Digital streams are multiplexed together to form higher-speed WAN circuits. DS-1 and DS-3 are the most common capacities.

Table 2: The North American Digital Hierarchy

Signal	Capacity	Number of DS-0s	Colloquial Name
DS-0	64 Kbps	1	Channel
DS-1	1.544 Mbps	24	T1
DS-1C	3.152 Mbps	48	T1C
DS-2	6.312 Mbps	96	T2
DS-3	44.736 Mbps	672	T3
DS-4	274.176 Mbps	4032	T4

In Europe, the Committee of European Postal and Telephone (CEPT) standardizes the European Digital Hierarchy, which is shown in Table 3.

The synchronous digital hierarchy (SDH) is an international standard for transmission over fiber-optic cabling. SDH defines a standard transmission rate of 51.84 Mbps, which is also called synchronous transport signal level 1, or STS-1. Higher rates of transmission are a multiple of the STS-1 rate. The STS rates are the same as the SONET optical carrier (OC) levels, which are shown in Table 4.

MAN Bandwidth

It is becoming common for companies to connect their sites to each other and to the Internet using an Ethernet link, rather than the WAN technologies mentioned in the previous section. Both new providers and traditional providers, who once offered only classic WAN options such as dial-up, T1, and frame relay, now offer Ethernet connectivity, which is often called Metro Ethernet. Metro Ethernet blends the capabilities and behavior of WAN technologies with those of Ethernet.

A Metro Ethernet customer can use a standard 10/100-Mbps Ethernet interface, or a Gigabit or 10-Gbps interface, to access the provider’s network. The customer can set up virtual circuits to reach other sites and to reach an Internet service provider (ISP). Metro Ethernet providers allow customers to add bandwidth as needed. Compared to adding WAN bandwidth, which can require months of negotiation with the provider, adding Metro Ethernet bandwidth often takes only a few minutes or hours. Metro Ethernet providers offer a wide range of bandwidth

Table 3: The European Digital Hierarchy

Signal	Capacity	Number of E1s
E0	64 Kbps	N/A
E1	2.048 Mbps	1
E2	8.448 Mbps	4
E3	34.368 Mbps	16
E4	139.264 Mbps	64

Table 4: The Synchronous Digital Hierarchy (SDH)

STS Rate	OC Level	Speed
STS-1	OC-1	51.84 Mbps
STS-3	OC-3	155.52 Mbps
STS-12	OC-12	622.08 Mbps
STS-48	OC-48	2.488 Gbps
STS-192	OC-192	9.953 Gbps
STS-768	OC-768	39.813 Gbps

options. In addition to the standard Ethernet data rates, many providers offer a 1-Mbps service and allow customers to add bandwidth in 1-Mbps increments.

Remote-Access Bandwidth

Remote offices (branch offices and telecommuters) may connect to an enterprise network using various remote-access technologies. The amount of bandwidth that these technologies offer depends on the provider and how much the user pays. It can also depend on physical constraints, such as how far the user is from the provider's central office and the condition of the wiring to the user's home. The bandwidth is generally sufficient for typical office applications, but may not be sufficient for bandwidth-intensive applications such as streaming video. Typical options include:

- A dial-up modem at 56 Kbps (a bad choice unless there is no other option)
- A cable modem at 256 Kbps upstream and 1 Mbps downstream
- Asymmetric digital subscriber link (ADSL) at 128 Kbps upstream and 256 Kbps downstream
- Symmetric DSL at 1.5 Mbps upstream and downstream
- Integrated services digital network basic rate interface (ISDN BRI) at 144-kbps upstream and downstream

Remote offices should connect to corporate headquarters via a virtual private network (VPN). At headquarters, a VPN concentrator must be carefully selected so that it has enough capacity to terminate VPN tunnels. As is the case with most internetworking devices, engineers should evaluate CPU speed and RAM-access speed. VPN concentrators can also benefit from specialized application specific integrated circuit (ASIC) hardware to speed up encryption and decryption of data sent across VPN tunnels.

Internetworking Device Capacity

The capacity of internetworking devices plays a major role in the overall capacity of a network. Internetworking devices include routers, bridges, switches, firewalls, wireless access points, concentrators, multiplexers, content switches, and load balancers. The capacity of an internetworking device is usually measured in packets-per-second (PPS) and means the number of packets in a second that the device can forward. The capacity of an internetworking device is affected by CPU power, the amount of RAM and disk storage, RAM and storage access speed, bus speed, and operating system and application software behavior. (Note that many internetworking devices do not have storage, so it may not be relevant.)

The software architecture of an internetworking device also affects its capacity. The speeds at which a device can handle buffering, queuing, dequeuing, matching addresses in tables such as routing tables, and applying differentiated services for high-priority traffic, all affect its capacity. The hardware architecture also affects capacity. For example, switches with a crossbar architecture are faster than older switches that used a shared bus.

Switches that avoid head-of-line blocking have higher capacity than those that do not. Head-of-line blocking is

a problem of input-queued switches that occurs when a packet waiting for a busy output interface delays packets behind it in the input queue, even when those other packets are destined for an idle output interface. Head-of-line blocking is similar to a movie theatre complex that does not allow anyone into any theatre because the first person in line is waiting for a movie theatre that is not yet empty from the last showing. To avoid this problem, movie theatre complexes should let everyone in and shuffle the customers who cannot get into their movie yet to the candy and popcorn stands. Similarly, an internetworking device can have a buffer or a set of output queues in which it can place packets as they await the availability of their output interface. More advanced features for avoiding head-of-line blocking include parallel iterative matching (PIM), which schedules incoming packets using randomization, and iSLIP, which enhances PIM and avoids the need for generating numerous random numbers, which can be problematic at very high speeds (Varghese 2004).

The PPS capacity for an internetworking device is the maximum rate at which the device can forward packets without dropping any. Vendors of internetworking devices often publish PPS ratings for their products, based on their own testing and independent tests. To test an internetworking device, testers place the device between traffic generators and a traffic checker. The generators send Ethernet packets ranging in size from 64 to 1518 bytes. By running multiple generators, devices can be tested with multiple interfaces. In a typical testing scenario, the testers send bursts of traffic through the device at an initial rate that is half of what is theoretically possible. If all packets are received, the rate is increased. If all packets are not received, the rate is decreased. This process is repeated until the highest rate at which packets can be forwarded without loss is determined. PPS values for small packets are much higher than those for large packets (simply because more small packets fit in a period of time than large packets do), so, of course, vendors usually publish a PPS rating that is based on the smallest packet size.

High-end internetworking devices can often forward packets at the theoretical maximum rate for the types of links they connect. (This is called "wire-speed forwarding.") The theoretical maximum rate is calculated by dividing bandwidth by packet size. The packet size includes headers and any protocol-required preambles, start/end frame delimiters, inter-packet gaps, and so on. Table 5 shows the theoretical maximum PPS for 100-Mbps Ethernet, based on packet size.

Testing the Capacity Plan

Capacity solutions should be tested. Testing should measure functionality, response time, throughput, availability, errors, and dropped packets. Tests should be designed that will characterize network performance and behavior under normal loads and higher-than-normal loads. Testing can be accomplished with network modeling tools and by implementing a prototype or pilot project. A prototype can be implemented on a test network in a lab. A pilot project is usually implemented on a production network with real users—but not all users, in case there are problems.

Table 5: Theoretical Maximum Packets per Second (PPS) for 100-Mbps Ethernet

Packet Size (in bytes)	Maximum PPS
64	148,800
128	84,450
256	45,280
512	23,490
768	15,860
1,024	11,970
1,280	9,610
1,518	8,120

Engineers should develop test objectives, test methods and scripts, and acceptance criteria. The criteria for declaring that a test has been passed or failed should be clear and accepted by the testers and users of the network. There is nothing worse than running tests, agreeing on the results, but disagreeing on the interpretation of the results. The types of testing that should be conducted include application, throughput, availability, and regression testing.

Application testing measures performance from a user's point of view and verifies correct functionality and low response time as the user does typical tasks such as start an application, switch between screens, open and store files, search for data, and so on. The tester can watch actual users or simulate users with a modeling tool. The testing should start with a set number of users, then gradually increase the number of users to expose any problems related to high network or server load.

Throughput testing measures the bits- or bytes-per-second rate that applications can achieve with a new capacity plan. As in application testing, throughput testing should start with a set number of users and then gradually increase the number to analyze network and device behavior under load.

Availability testing makes sure the network does not fail (become unavailable) because of the changes related to the new capacity plan. It can also test for bit errors on WAN links, CRC errors on LAN links, and dropped packets. Finally, regression testing is also important, whereby the engineer tries to make sure the new implementation will not break applications or devices that were known to work before the new plan was developed.

The results of testing the new capacity plan may call for some changes to the plan. If the plan was developed in a systematic way using the processes explained in this chapter, then it should not require major changes, but fine-tuning is often necessary. After the plan is implemented and users start maximizing their use of the network, then bigger changes may become necessary. Network capacity is like closet space—it is never enough.

Planning for the Future

After a capacity plan is implemented, it must be monitored. Network engineers need to be vigilant about measuring

bandwidth utilization, throughput, availability, accuracy, delay and jitter, and response time. Engineers and their managers need to work with business and operational managers to learn about new applications and uses for the network that were not anticipated.

Parkinson's law applies to networks. Developed by C. Northcote Parkinson (1958), Parkinson's law states that "work expands so as to fill the time available for its completion." Parkinson based his law on his experiences in the British Civil Service, where he noted that the number of employees at the Colonial Office increased even though Britain's empire was no longer growing. In a more general sense, Parkinson's law means that the demand on a resource expands to match the supply of the resource. Parkinson's law is often used in the computer industry to call attention to the fact that the amount of data tends to grow to the point at which it fills the space available for storage; CPU power is consumed by new applications; and network traffic expands to fill the capacity available to it.

CONCLUSION

Capacity planning is the process of determining the resources that will be needed for a network to support the traffic that is offered to it. Resources include LAN and WAN bandwidth, server capacity, and internetworking device capacity. LAN and WAN bandwidth, as measured in bits-per-second rates, plays a major role in capacity planning, but it is not the only component of a good plan. Servers and internetworking devices also need sufficient CPU power, RAM and disk storage, and fast access to RAM and storage. They also need optimized architectures and the ability to process a high rate of packets per second. Capacity planning must take into account traffic behavior such as acknowledgments, broadcast packets, frame sizes, and windowing and flow-control mechanisms. Classifying network traffic as background versus transactional helps distinguish the types of traffic a network must carry. Classifying the service requirements of traffic helps determine the special processing that may be needed for some types of traffic.

Capacity planning is not an easy task. For one thing, it requires anticipating what users will do with the network in the future. In addition, network systems are complex, with many different components that can affect capacity. Nonetheless, by following a structured, systematic process that is based on gathering information about business drivers, applications, network architecture and performance, and the types of traffic and traffic patterns the network must support, effective capacity planning can be achieved. Capacity planning is also facilitated by a modular, hierarchical network topology in which future needs can be met by changing one layer of the architecture, rather than the entire structure.

Capacity planning does not stop with an implementation of the plan. Network usage tends to increase until the capacity of the network is reached. As it was said about the baseball diamond in the middle of Iowa in the movie *Field of Dreams*, "if you build it, they will come." Expect a well-functioning network to get used and overused to the point at which it needs more capacity. A network engineer's job is never done.

GLOSSARY

Bandwidth: The bits-per-second rate that a network can handle.

Capacity: The potential for a network to accommodate the network traffic that is offered to it.

Capacity Planning: The process of determining the resources that will be needed for a network to support the traffic that is offered to it.

Head-of-Line Blocking: A problem of input-queued switches that occurs when a packet waiting for a busy output delays packets behind it in the input queue, even when those other packets are destined for an idle output.

Jitter: A measure of the variability over time of the average delay across a network.

Packets per Second (PPS): The rate at which an inter-networking device can forward packets.

Throughput: A measure of how much traffic can be passed across a network path in a stated period of time.

Wire-Speed Forwarding: Relaying packets at the theoretical maximum rate for the type of connected network.

INTRODUCTION

Teletraffic theory is the application of mathematics to the measurement, modeling, and control of traffic in telecommunications networks (Willinger and Paxson 1998). The aim of traffic modeling is to find stochastic processes to represent the behavior of traffic. Working at the Copenhagen Telephone Company in the 1910s, A. K. Erlang famously characterized telephone traffic at the call level by certain probability distributions for arrivals of new calls and their holding times. Erlang applied the traffic models to estimate the telephone switch capacity needed to achieve a given call-blocking probability. The Erlang blocking formulas had tremendous practical interest for public carriers because telephone facilities (switching and transmission) involved considerable investments. Over several decades, Erlang's work stimulated the use of queuing theory, and applied probability in general, to engineer the public switched telephone network.

Packet-switched networks started to be deployed on a large scale in the 1970s. Like circuit-switched networks, packet networks are designed to handle a certain traffic capacity. Greater network capacity leads to better network performance and user satisfaction, but requires more investment by service providers. The network capacity is typically chosen to provide a target level of quality of service (QoS). QoS is the network performance seen by a packet flow, measured mainly in terms of end-to-end packet loss probability, maximum packet delay, and delay jitter or variation (Firoiu et al. 2002). The target QoS is derived from the requirements of applications. For example, a real-time application can tolerate end-to-end packet delays up to a maximum bound.

Unfortunately, teletraffic theory from traditional circuit-switched networks could not be applied directly

to emerging packet-switched networks for a number of reasons. First, voice traffic is fairly consistent from call to call, and the aggregate behavior of telephone users does not vary much over time. However, packet networks carry more diverse data traffic, for example, e-mail, file transfers, remote log-in, and client/server transactions. Data applications are typically "bursty" (highly variable over time) and vary in behavior from one another. Also, the traffic diversity has increased with the growing number of multimedia applications. Second, traffic is controlled differently in circuit- and packet-switched networks. A circuit-switched telephone call proceeds at a constant bit rate after it is accepted by the network. It consumes a fixed amount of bandwidth at each telephone switch. In contrast, packet flows may be subjected to access control (rate enforcement at the network boundary); flow control (the destination slowing down the sender); congestion control (the network slowing down the sender); and contention within the network from other packet flows. Thus, packet traffic exhibits much more complex behavior than circuit-switched voice.

Teletraffic theory for packet networks has seen considerable progress in recent decades (Adas 1997; Frost and Melamed 1994; Michiel and Laevens 1997; Park and Willinger 2000). Significant advances have been made in long-range dependence, wavelet, and multifractal approaches. At the same time, traffic modeling continues to be challenged by evolving network technologies and new multimedia applications. For example, wireless technologies allow greater mobility of users. Mobility must be an additional consideration for modeling traffic in wireless networks (Thajchayapong and Peha 2006; Wu, Lin, and Lan 2002). Traffic modeling is clearly an ongoing process

without a real end. Traffic models represent our best current understanding of traffic behavior, but our understanding will change and grow over time.

This chapter presents an overview of commonly used traffic models reflecting recent developments in the field. The first step in modeling is understanding the statistical characteristics of the traffic. The first section reviews common statistical measures such as burstiness, long-range dependence, and frequency analysis. Next, we examine common continuous-time and discrete-time source models. These models are sufficiently general to apply to any type of traffic, but application-specific models are tailored more closely to particular applications. We highlight studies of the major Internet applications: World Wide Web, peer-to-peer file sharing, and streaming video. In the last section, we examine two major ways that the network affects the source traffic. First, traffic sources can be “policed” at the network access. Second, the dynamics of TCP flows (the majority of Internet traffic) are affected by network congestion and active queue-management schemes at network nodes.

Packets, Flows, and Sessions

Some terminology should be introduced at this point because traffic can be viewed at different levels, as shown in Figure 1. When the need arises, a host will establish a session with another host. A session is associated with a human activity. For example, a client host will open a TCP connection to port 21 on a server to initiate a file transfer protocol (FTP) session. The TCP connection will be closed at the end of the FTP session. Or a session may be viewed as the time interval when a dial-up user is connected to an Internet service provider (ISP). For connection-oriented networks such as asynchronous transfer mode (ATM), a session is a call established and terminated by signaling messages. Traffic modeling at the session (or call) level consists of characterizing the start times and duration of each session.

During a session, each host may transmit one or more packet flows to the other host (Roberts 2004). Although the term is used inconsistently in the literature, a *flow* is commonly considered to be a series of closely spaced packets in one direction between a specific pair of hosts. Packets in a flow usually have common packet header fields such as protocol ID and port numbers (in addition to source and

destination addresses). For example, an FTP session involves two packet flows between a client and server: one flow is the control stream through TCP port 21, and the second flow is the data stream (through a negotiated TCP port). Traffic modeling at the flow level consists of characterizing the random start times and durations of each flow.

TCP flows have been called “elephants” or “mice,” depending on their size. An elephant’s duration is longer than the TCP slow start phase (the initial rate increase of a TCP connection until the first dropped packet). Because of their short duration, mice are subject to TCP’s slow start but not to TCP’s congestion-avoidance algorithm. Less-common terms are *dragonflies*, flows shorter than 2, and *tortoises*, flows longer than 15 minutes (Brownlee and Claffy 2002). Traffic measurements have suggested that 40 to 70% of Internet traffic consists of short flows, predominantly Web traffic. Long flows (mainly non-Web traffic) are a minority of the overall traffic, but have a significant effect because they can last hours to days.

Viewed in more detail, a flow may be made up of intermittent bursts, each burst consisting of consecutively transmitted packets. Bursts may arise in window-based protocols, in which a host is allowed to send a window of packets, then must wait to receive credit to send another window. Another example is an FTP session, in which a burst could result from each file transferred. If a file is large, it will be segmented into multiple packets. A third example is a talkspurt in packet voice. In normal conversations, a person alternates between speaking and listening. An interval of continuous talking is a talkspurt, which results in a burst of consecutive packets.

Finally, traffic can be viewed at the level of individual packets. This level is concerned only with the arrival process of packets and ignores any higher structure in the traffic (bursts, flows, sessions). The majority of research (and this chapter) address traffic models mainly at the packet level. Studies at the packet level are relatively straightforward because packets can be easily captured for minutes or hours.

Studies of traffic flows and sessions require collection and analysis of greater traffic volumes because flows and sessions change over minutes to hours, so hours or days of traffic need to be examined. For example, one analysis involved a few packet traces of several hours each (Barakat et al. 2003). Another study collected eight days of traffic (Brownlee and Claffy 2002).

Figure 1: Levels of traffic

The Modeling Process

Traffic models reflect our best knowledge of traffic behavior. Traffic is easier to characterize at sources than within the network because flows of traffic mix together randomly within the network. When flows contend for limited bandwidth and buffer space, their interactions can be complex to model. The “shape” of a traffic flow can change unpredictably as the flow progresses along its route. On the other hand, source traffic depends only on the rate of data generated by a host independent of other sources.

Our knowledge is gained primarily from traces (measurements) of past traffic, consisting of packet arrival times, packet header fields, and packet sizes. A publicly available trace of Ethernet traffic recorded in 1989 is shown in Figure 2. A trace of *Star Wars IV* encoded by MPEG (Moving Picture Coding Experts Group) 4 at medium quality is shown in Figure 3 (data rate per frame). Traffic can be measured by packet sniffers or protocol analyzers, which are specialized pieces of hardware and software for recording packets at link rates (Thompson, Miller, and Wilder 1997). Common sniffers are tcpdump, Snort, and Ethereal. These can be easily connected to transmission links, local area networks, or mirrored ports on switches and routers. Also, traffic volume is routinely recorded by routers as part of the simple network management protocol (SNMP). In addition, some NetFlow-capable routers are able to record simple flow information (e.g., flow start/stop times, number of bytes, and number of packets).

Figure 2: Ethernet traffic trace

Figure 3: Trace of *Star Wars IV* encoded at medium quality MPEG-4

One of the practical difficulties in traffic modeling is collecting and analyzing large sets of traffic measurements. Traffic can be highly variable, even between two similar types of sources. For example, one video might have many scene changes, reflected by frequent spikes in the source rate, while another might have few scene changes, resulting in a smoother source rate. Therefore, it is good practice to collect measurements from many sources or over many time periods, and then look for common aspects in their behavior. In probabilistic terms, each traffic trace is a single realization or sample of the traffic behavior. A small sample set could give a misleading portrayal of the true traffic behavior.

A good choice for a stochastic model should exhibit accuracy and universality. *Accuracy* refers to a close fit between the model and actual traffic traces in statistical terms. Sometimes accuracy is judged by the usefulness of a model to predict future behavior of a traffic source. *Universality* refers to the suitability of a model for a wide range of sources. For example, an MPEG traffic model should be equally applicable to any particular video source, not just to *Star Wars* (although the parameter values of the model may need to change to fit different sources).

Our knowledge of traffic is augmented from analyses and simulations of protocols. For example, we know that TCP sources are limited by the TCP congestion-avoidance algorithm. The TCP congestion-avoidance algorithm has been analyzed extensively, and TCP sources have been simulated to investigate the interactions between multiple TCP flows to verify the stability and fairness of the algorithm.

Ultimately, a traffic model is a mathematical approximation for real traffic behavior. There is typically more than one possible model for the same traffic source, and the choice depends somewhat on subjective judgment. The choice often lies between simple, less accurate models and more complex, accurate models. An ideal traffic model would be both simple to use and accurate, but there is usually a trade-off between simplicity and accuracy. For example, a common time series model is the p -order autoregressive model (discussed later). As the order p increases, the autoregressive model can fit any data more accurately, but its complexity increases with the number of model parameters.

Uses of Traffic Models

Given the capability to capture traffic traces, a natural question is why traffic models are needed. Would not traffic measurements be sufficient to design, control, and manage networks? Indeed, measurements are useful and necessary for verifying the actual network performance. However, measurements do not have the level of abstraction that makes traffic models useful. Traffic models can be used for hypothetical problem solving, whereas traffic measurements only reflect current reality. In probabilistic terms, a traffic trace is a realization of a random process, whereas a traffic model is a random process. Thus, traffic models have universality. A traffic trace gives insight about a particular traffic source, but a traffic model gives insight about all traffic sources of that type.

Traffic models have many uses, but at least three major ones. One important use of traffic models is to allow proper dimensions for network resources for a target level of QoS. It was mentioned above that Erlang developed models of voice calls to estimate telephone switch capacity to achieve a target call-blocking probability. Similarly, models of packet traffic are needed to estimate the bandwidth and buffer resources to provide acceptable packet delays and packet-loss probability. Knowledge of the average traffic rate is not sufficient. It is known from queuing theory that queue lengths increase with the variability of traffic (Kleinrock 1976). Hence, an understanding of traffic burstiness or variability is needed to determine sufficient buffer sizes at nodes and link capacities (Barakat et al. 2003).

A second important use of traffic models is to verify network performance under specific traffic controls. For example, given a packet-scheduling algorithm, it would be possible to evaluate the network performance resulting from different traffic scenarios. For another example, a popular area of research is new improvements to the TCP congestion-avoidance algorithm. It is critical that any algorithm is stable and allows multiple hosts to share bandwidth fairly, while sustaining a high throughput. Effective evaluation of the stability, fairness, and throughput of new algorithms would not be possible without realistic source models.

A third important use of traffic models is admission control. In particular, connection-oriented networks such as ATM depend on admission control to block new connections to maintain QoS guarantees. A simple admission strategy could be based on the peak rate of a new connection; a new connection is admitted if the available bandwidth is greater than the peak rate. However, that strategy would be overly conservative because a variable bit-rate connection may need significantly less bandwidth than its peak rate. A more sophisticated admission strategy is based on effective bandwidths (Kelly 1996). The source traffic behavior is translated into an effective bandwidth between the peak rate and the average rate, which is the specific amount of bandwidth required to meet a given QoS constraint. The effective bandwidth depends on the variability of the source.

SOURCE TRAFFIC STATISTICS

This section gives an overview of general statistics to characterize source traffic. The traffic may be represented by its time-varying rate $X(t)$ in continuous time, or X_n in discrete time. In practice, we are often measuring the amount of data generated over short periodic intervals, and then the traffic rate is the discrete-time process X_n . A discrete-time process is also easier for computers to record and analyze (as a numerical vector) than a continuous-time process. On the other hand, it might be preferable to view the traffic rate as a continuous-time process $X(t)$ for analysis purposes, because the analysis in continuous time can be more elegant. For example, video source rates are usually characterized by the data per frame, so X_n would represent the amount of data generated for the n th frame. But X_n could be closely approximated by a suitable continuous-time process $X(t)$ for convenience, if analysis

is easier in continuous time. Alternatively, traffic may be viewed as a point process defined by a set of packet arrival times $\{t_1, t_2, \dots\}$ or equivalently a set of interarrival times $\tau_n = t_n - t_{n-1}$.

When a traffic trace is examined, one of the first analysis steps is calculation of various statistics. Statistics can suggest an appropriate traffic model. For example, an exponential autocorrelation function is suggestive of a first-order autoregressive process (discussed later).

Simple Statistics

The traffic rate is usually assumed to be a stationary or at least wide sense stationary (WSS) process for convenience, although stationarity of observed traffic is impossible to prove because it is a property over an infinite (and unobservable) time horizon. WSS means that the mean $E(X_t)$ is constant over all time t , and the autocovariance function:

$$R_X(t, s) = E[(X_t - E(X_t))(X_s - E(X_s))] \quad (1)$$

depends strictly on the lag $|t - s|$ and can be written as $R_X(t - s)$.

First-order statistics such as peak rate and mean rate are easy to measure. The marginal probability distribution function can be estimated by a histogram. Second-order statistics include the variance and autocorrelation function:

$$\rho_X(t - s) = R_X(t - s)/R_X(0). \quad (2)$$

An example of the autocorrelation function estimated for the Ethernet traffic from Figure 2 is shown in Figure 4 (lag is in units of 10 ms). The variance indicates the degree of variability in the source rate, while the autocorrelation function gives an indication of the persistence of bursts (long-range dependence is discussed below). The shape of the autocorrelation function is informative about the choice of a suitable time-series model (discussed below). Equivalently, the power spectral density function, which is the Fourier transform of the autocorrelation function, is just as informative.

Figure 4: Autocorrelation function for Ethernet traffic

Burstiness Measures

For variable bit-rate sources, “burstiness” is a quantity reflecting the source’s variability. While *burstiness* is easy to understand intuitively, there is unfortunately not a universally agreed-on definition. The simplest definition of *burstiness* is the ratio of peak rate to mean rate. This does not reveal much information about the source because it does not capture how long the peak rate can be sustained (which would have the greatest effect on queuing).

Another possibility is the squared coefficient of variation, treating the traffic rate as samples of a random variable X . The squared coefficient of variation $c^2(X) = \text{var}(X)/E^2(X)$ is a normalized version of the variance of X (normalized by dividing by the squared mean).

A related but more sophisticated measure is the index of dispersion of counts, or IDC, $I_c(t) = \text{var}(N(t))/E(N(t))$, the variance of the number of arrivals up to time t normalized by the mean number of arrivals (Gusella 1991). The number of arrivals up to time t , $N(t)$, is the number of interarrival times fitting in the interval $(0, t)$. Thus, the IDC captures similar but more time-scale-dependent information than the coefficient of variation $c^2(X)$.

Perhaps a more accurate measure is the index of dispersion of workload (IDW), $I_w(t) = \text{var}(Y(t))/E(Y(t))$, where $Y(t)$ is the total amount of data that has arrived up to time t . The workload takes into account the amount of data in packets, not only the number of packets (Fendick et al. 1991).

Long-Range Dependence and Self-Similarity

Measurements of Ethernet, MPEG video, and World Wide Web traffic have pointed out the importance of self-similarity in network traffic (Beran 1994; Crovella and Bestavros 1997; Erramilli et al. 2002; Leland et al. 1994; Paxson and Floyd 1995; Sahinoglu and Tekinay 1999). Suppose the traffic rate is a discrete-time WSS process X_n with mean $\bar{X}$ and autocorrelation function $\rho_X(k)$. For positive integer m , a new process $X_n^{(m)}$ is constructed as shown

below by averaging the original process over nonoverlapping blocks of size m (Figure 5):

$$X_n^{(m)} = (X_{nm} + \dots + X_{nm+m-1})/m. \quad (3)$$

The new process $X_n^{(m)}$ is WSS with mean $\bar{X}$ and autocorrelation function $\rho_X^{(m)}(k)$. The process X_n is asymptotically second-order self-similar if $\rho_X^{(m)}(k) = \rho_X(k)$ for large m and k . Essentially, self-similarity means that the rescaled process $a^{-H}X_{an}$ has the same statistical properties as the original process X_n over a wide range of scales $a > 0$ and some parameter $0 < H < 1$. This would not be true for a process such as the Poisson process, which tends to become smoother for large m . The Hurst parameter H is a measure of self-similarity.

Self-similarity is manifested by a slowly decaying autocorrelation function:

$$\rho_X(k) \sim ck^{2(H-1)} \quad (4)$$

for some $c > 0$ as $k \rightarrow \infty$. Self-similarity implies long-range dependence, which is a property of the asymptotic rate of decay of the autocorrelation function. A short-range dependent (SRD) process has an autocorrelation function that decays at least as fast as exponentially:

$$\rho_X(k) \sim \gamma^{-k} \quad (5)$$

for large k and some constant γ . Equivalently, the sum $\sum_k \rho_X(k)$ is finite. A long-range dependent (LRD) process has an autocorrelation function that decays slower than exponentially—for example, hyperbolically $\rho_k(k) \rightarrow k^{2(H-1)}$ for $0.5 < H < 1$. In this case, the sum $\sum_k \rho_X(k)$ is infinite.

Self-similarity and long-range dependence are important statistical characteristics because they are believed to have a major effect on queuing performance (Erramilli et al. 2002). Essentially, bursts of LRD traffic tend to be more persistent, thereby causing longer queue lengths than estimated for traditional SRD traffic such as Poisson.

Multiresolution Time Scale

The establishment of long-range dependence in network traffic prompted interest in the analysis of self-similar processes using time-scale methods, particularly wavelets (Abry and Veitch 1998; Ma and Ji 2001). Wavelet transforms are a useful tool for examining processes with scaling behavior, referred to as multiresolution analysis. They are most easily approached and motivated from the familiar Fourier transform, which decomposes a process (or signal) into a weighted sum of sinusoids. That is, the Fourier transform gives information about the frequency components but not any time information (where the frequency components occur in time). This is well suited for stationary processes but not for nonstationary processes. In contrast, the wavelet transform gives both time and frequency information. The short-time Fourier transform can handle nonstationary processes by taking windows of the signal, but there is a trade-off between time and frequency resolution.

A continuous wavelet transform decomposes a process into a weighted sum of wavelet functions. The wavelet functions are derived from a “mother wavelet” $\psi(t)$ —for example, the Haar wavelet, Morlet wavelet, Mexican Hat, or Daubechies family of wavelets. The set of wavelets is generated by dilating the mother wavelet

$$\psi_s(t) = \frac{1}{\sqrt{s}} \psi\left(\frac{t}{s}\right), \quad (6)$$

where s is the scale parameter. Larger scales correspond to dilated signals and give a global view of the process (low frequencies), while the opposite holds for smaller scales. The continuous wavelet transform of a process $X(t)$ is

$$CWT(b, s) = \frac{1}{\sqrt{|s|}} \int_{-\infty}^{\infty} X(t) \psi\left(\frac{t-b}{s}\right) dt, \quad (7)$$

where b is the translation parameter.

In order to facilitate computer processing, it is necessary to discretize the transform by sampling the time-frequency plane. The discrete wavelet transform (DWT) analyzes a process at dyadic scales using inner products at shifts equal to the length of the wavelet. It is computed by passing the process through a series or bank of filters. The first level consists of parallel low-pass and high-pass filters, followed by downsampling by two. The level 1 coefficients are output from the downsampled high-pass filter. The output of the low-pass filter goes again through another filter stage (with high- and low-pass filters, and downsampling) to increase the frequency resolution. The level 2 coefficients are output from the high-pass filter in the second stage, and additional stages of filters can be used in the same manner. The result is a set of coefficients that represent the process as a low-resolution approximation and additional approximations of increasing resolutions.

An early use of the DWT was estimation of the Hurst parameter (Abry and Veitch 1998; Roughan, Veitch, and Abry 2000). Wavelet transforms have been used to analyze video and Ethernet traffic for the purpose of accurately synthesizing traffic with both long- and short-range dependence (Ma and Ji 2001).

Scaling

Recent studies of network traffic have found complex scaling behavior at small time scales (Riedi et al. 1999; Gilbert, Willinger, and Feldmann 1999; Abry et al. 2002). Previous studies had focused on monofractal models, such as self-similar processes. These show invariance across a wide range of scales and can be characterized by a single scaling law, for example, the Hurst parameter H .

Multifractal models have been found to better explain scaling behavior at small time scales. Loosely speaking, multifractal models have local scaling properties dependent on a time-varying $h(t)$, the local Hölder exponent, instead of a constant Hurst parameter. Intervals during which $h(t) < 1$ show bursts, while intervals during which $h(t) > 1$ correspond to small fluctuations. In traffic measurements, the local scaling $h(t)$ appears to change randomly in time.

CONTINUOUS-TIME SOURCE MODELS

Traffic models can be continuous-time or discrete-time. In continuous time, we are interested in a stochastic process to represent the time-varying source rate $X(t)$ or the set of packet arrival times $\{t_1, t_2, \dots\}$.

Traditional Poisson Process

In traditional queuing theory, the Poisson arrival process has been a favorite traffic model for data and voice. The traditional assumption of Poisson arrivals has often been justified by arguing that the aggregation of many independent and identically distributed renewal processes tends to a Poisson process when the number increases (Sriram and Whitt 1986). Poisson arrivals with mean rate λ are separated by interarrival times $\{\tau_1, \tau_2, \dots\}$ that are i.i.d. (independent and identically distributed) according to an exponential probability distribution function $p(\tau) = \lambda e^{-\lambda\tau}$, $\tau \geq 0$. Equivalently, the number of arrivals up to time t is a Markov birth process with all birth rates of λ .

The Poisson arrival process has several properties that make it appealing for analysis.

- It is memoryless in the sense that, given that the previous arrival occurred T time ago, the time to the next arrival will be exponentially distributed with mean $1/\lambda$, regardless of T . In other words, the waiting time for the next arrival is independent of the time of the previous arrival. This memoryless property simplifies analysis because future arrivals do not need to take into account the history of the arrival process.
- The number of arrivals in any interval of length t will have a Poisson probability distribution with mean λt .
- The sum of two independent Poisson arrival processes with rates λ_1 and λ_2 is a Poisson process with rate $\lambda_1 + \lambda_2$. This is convenient for analysis because traffic flows are multiplexed in a network.
- Suppose a Poisson arrival process with rate λ is randomly split, meaning that each arrival is diverted to

a first process with probability p or a second process with probability $1 - p$. The first process is a Poisson arrival process with rate $p\lambda$ and the second process is another Poisson process with rate $(1 - p)\lambda$.

Despite the attractiveness of the Poisson model, its validity for real traffic has often been questioned. Barakat et al. (2003) offered evidence that flow arrivals on Internet backbone links are well matched by a Poisson process.

For large populations in which each user is independently contributing a small portion of the overall traffic, user sessions can be assumed to follow a Poisson arrival process (Roberts 2004). Based on traces of wide area TCP traffic, Poisson arrivals appear to be suitable for traffic at the session level when sessions are human-initiated—for example, interactive TELNET and FTP sessions (Paxson and Floyd 1995). However, the Poisson model does not hold for machine-initiated sessions or for any packet-level traffic.

Simple On/Off Model

The simple on/off model is motivated by sources that alternate between active and idle periods. An obvious example is speech, during which a person is either talking or listening. The time in the active state is exponentially distributed with mean $1/\alpha$, and the time in the idle state is exponentially distributed with mean $1/\beta$. The state of the source can be represented by the two-state continuous-time Markov chain shown in Figure 6.

In the active state, the source is generating packets at a constant rate $1/T$ —that is, interarrival times between packets are a constant T . In the idle state, no packets are generated. This on/off model can be considered a simple example of a modulated process, which is a combination of two processes. The basic process is a steady stream of packets at a constant rate $1/T$. The basic process is multiplied by a modulating process, which is the Markov chain shown in Figure 6 (the active state is equivalent to 1, while the idle state is equivalent to 0). The modulation has the effect of canceling the packets during the idle state. The resulting on/off traffic is shown in Figure 7.

Suppose that packets are generated as a Poisson process with rate λ during active periods, instead of a constant

Figure 6: Two-state Markov chain

Figure 7: On/off traffic as example of a modulated process

rate process. This process is an interrupted Poisson process (IPP). The effect of the modulating process is to cancel or “interrupt” a normal Poisson process during idle states.

Markov Modulated Poisson Process

Although the Poisson process is attractive as a traffic model, it is obviously unrealistic in one aspect: the arrival rate λ is constant. If we consider the aggregate of multiple packet speech flows, the flow rate will not be constant because speech conversations are starting and terminating at random times. The flow rate will drop whenever a speech conversation stops and will increase whenever a new conversation begins.

Suppose N speech conversations are multiplexed, and each speech conversation is an IPP. The aggregate flow will be a Markov modulated Poisson process (MMPP) (Heffes and Lucantoni 1986). The basic process is a Poisson process with rate $\lambda(t)$. The rate is modulated as $\lambda(t) = n(t)\lambda$, where $n(t)$ is the number of speech conversations that are active at time t . In this case, $n(t)$ is the state of a continuous-time Markov chain (specifically, a birth-death process) shown in Figure 8. The MMPP preserves some of the memoryless property of the Poisson process and can be analyzed by Markov theory. However, the complexity of the analysis increases with N , so the value of N is usually small.

Stochastic Fluid Model

Fluid models depart from traditional point process models by ignoring the discrete nature of packets. Consider again the MMPP model. The traffic rate is $X(t) = n(t)\lambda$, where $n(t)$ is again the number of active sources at time t represented by the birth-death process in Figure 8. The packet process is a complicated point process if one attempts to characterize the packet arrival times $\{t_1, t_2, \dots\}$ shown in Figure 9.

Instead, it is easier to simply use the process $X(t)$ as the traffic model for most purposes (Cassandras et al. 2002). According to the stochastic fluid model, an active source transmits data at a constant rate, λ like a fluid flow, instead of in discrete packets. The stochastic fluid model is the aggregation of N such fluid sources. The stochastic

Figure 8: Birth-death process for number of active sources

Figure 9: Packet arrivals in MMPP model

fluid buffer is attractive for its simplicity and tractability for fluid buffer flow analysis (Anick, Mitra, and Sondhi 1982).

Fractional Brownian Motion

The definition of fractional Brownian motion (FBM) is similar to the well-known Brownian motion except that it is generalized to depend on a Hurst parameter H . A fractional Brownian motion $X(t)$ is a Gaussian continuous process starting at $X(0) = 0$, with zero mean and variance $\text{var}(X(t)) = t^{2H}$, and has stationary increments that are normally distributed with zero mean and variance $\sigma^2 t^{2H}$. Its autocorrelation function is

$$R(s, t) = E(X(s)X(t)) = \frac{1}{2}(s^{2H} + t^{2H} - |s - t|^{2H}), \quad (8)$$

which shows that regular Brownian motion is a special case when $H = 0.5$. For $0.5 < H < 1$, the autocorrelation function exhibits long-range dependence with Hurst parameter H .

Fractional Brownian motion has been proposed as a model for “free traffic” (unconstrained by network resources) aggregated from many independent sources (Norros 1995). The model is attractive because it is fairly straightforward for analysis and characterization of long-range dependence. It is also tractable for queuing (fluid buffer) analysis, unlike most discrete-time models.

DISCRETE-TIME SOURCE MODELS

In discrete time, we are interested in a stochastic process X_n to represent the source rate sampled at discrete times $n = 1, 2, \dots$. In a sense, there is little difference between continuous-time and discrete-time models because there are stochastic processes in continuous or discrete time that behave similarly to each other. Discrete-time processes can be closely approximated by continuous-time processes, and vice versa. Discrete-time models may be preferred when analysis is easier in discrete time, or when network simulations are carried out in discrete time (versus discrete-event simulations).

Time series are commonly assumed to be consecutive measurements of some random phenomenon taken at equally spaced time intervals. Classical time-series analysis using ARIMA (autoregressive integrated moving average) models largely follows the Box and Jenkins (1970) method.

Time Series

The simplest time-series model is perhaps the autoregressive (AR) process. A p th order autoregressive model, denoted $\text{AR}(p)$, has the form:

$$X_n = (\alpha_1 X_{n-1} + \dots + \alpha_p X_{n-p}) + e_n, \quad (9)$$

where $\{\alpha_1, \dots, \alpha_p\}$ are coefficients and e_n is the residual process assumed to be i.i.d. zero-mean normal random variables. Each point in the process is a linear combination

of previous points and a random noise. The coefficients are found by linear regression, or fitting the exponential autocorrelation function to the observed autocorrelation function.

AR models are particularly motivated by studies of packet video with low motion (e.g., videoconferencing), where X_n is the bit rate of the n th video frame (Maglaris et al. 1988). There is a strong correlation between the bit rates of successive frames because of the nature of low-motion video and interframe coding algorithms.

An autoregressive moving average (ARMA) model of order (p, q) , denoted $\text{ARMA}(p, q)$, has a more general form than the AR process:

$$X_n = (\alpha_1 X_{n-1} + \dots + \alpha_p X_{n-p}) + (e_n + \beta_1 e_{n-1} + \dots + \beta_q e_{n-q}), \quad (10)$$

where $\{\alpha_1, \dots, \alpha_p, \beta_1, \dots, \beta_q\}$ are coefficients. The moving average terms constitute a linear combination of prior noise samples. The ARMA process has also been proposed for a video source model (Grunenfelder et al. 1991).

The autoregressive integrated moving average process, denoted $\text{ARIMA}(p, d, q)$ with integer d , is a generalization of ARMA processes. Define B as the backward operator $BX_n = X_{n-1}$. A succinct representation of an ARMA process is

$$\phi(B)X_n = \theta(B)e_n, \quad (11)$$

where the polynomials are $\phi(B) = 1 - \alpha_1 B - \dots - \alpha_p B^p$ and $\theta(B) = 1 + \beta_1 B + \dots + \beta_q B^q$. In addition, define the difference operator $\nabla X_n = X_n - X_{n-1}$. An $\text{ARIMA}(p, d, q)$ process has the form:

$$\phi(B)\nabla^d X_n = \theta(B)e_n \quad (12)$$

The parameter d is the number of times that the time series is differenced (i.e., converting each i th element of the series into its difference from the $(i-j)$ th element). The reason for differencing is usually to convert a nonstationary time series into a stationary series by removing seasonal dependencies. The parameters of the autoregressive and moving average components are computed for the series after the differencing is done.

A fractional ARIMA, denoted F-ARIMA(p, d, q), is a generalization of an ARIMA allowing noninteger values of d . With $0 < d < 0.5$, the F-ARIMA(p, d, q) is stationary with long-range dependence with Hurst parameter $H = d + 0.5$.

Box–Jenkins Method

The Box–Jenkins method proceeds in three stages: model identification, model estimation, and model validation. Model identification is perhaps the most challenging, and depends largely on the expert judgment of the analyst. The analyst needs to examine the stationarity of the time series, including seasonality (periodic components) and trends (nonperiodic linear or nonlinear components). Seasonality and trends are subtracted from the series in order to obtain a stationary process. Differencing is another technique to convert a nonstationary series into

a stationary one. After stationarity is achieved, the analyst must decide on the order (p, q) of the ARMA model, largely based on examination of the autocorrelation function.

With the order of the ARMA process decided, the next step is estimation of the model parameters (coefficients). The most common methods are least squares regression or maximum likelihood estimation.

The last step examines the validity of the chosen ARMA model. If the model was fitted properly, the residuals should appear like white noise. That is, residuals should be stationary, mutually independent, and normally distributed.

APPLICATION-SPECIFIC MODELS

Network traffic is obviously driven by applications. The most common applications that come to mind might include Web, e-mail, peer-to-peer file sharing, and multimedia streaming. One traffic study of Internet backbone traffic showed that Web traffic is the single largest type of traffic, on the average more than 40% of total traffic (Fraleigh et al. 2003). However, on a minority of links, peer-to-peer traffic was the heaviest type of traffic, indicating a growing trend. Streaming traffic (e.g., video and audio) constitute a smaller but stable portion of the overall traffic. E-mail is an even smaller portion of the traffic.

It is possible to apply the general-purpose continuous-time and discrete-time traffic models from the previous section. However, it is logical that specialized traffic models may work better for particular applications. Therefore, traffic analysts have attempted to search for models tailored to the most common Internet applications (Web, peer-to-peer, and video).

Web Traffic

The World Wide Web is a familiar client/server application. Most studies have indicated that Web traffic is the single largest portion of overall Internet traffic, which is not surprising, considering that the Web browser has become the preferred user-friendly interface for e-mail, file transfers, remote data processing, commercial transactions, instant messages, multimedia streaming, and other applications.

An early study focused on the measurement of self-similarity in Web traffic (Crovello and Bestavros 1997). Self-similarity had already been found in Ethernet traffic. Based on days of traffic traces from hundreds of modified Mosaic Web browser clients, it was found that Web traffic exhibited self-similarity with the estimated Hurst parameter H in the range 0.7 to 0.8. More interestingly, it was theorized that Web clients could be characterized as on/off sources with heavy-tailed on periods. In previous studies, it had been demonstrated that self-similar traffic can arise from the aggregation of many on/off flows that have heavy-tailed on or off periods. A probability distribution is heavy-tailed if the asymptotic shape of the distribution is hyperbolic:

$$\Pr(X > x) \sim x^{-\gamma} \quad (13)$$

as $x \rightarrow \infty$, for $0 < \gamma < 2$. Heavy tails imply that very large values have non-negligible probability. For Web clients,

on periods represent active transmissions of Web files, which were found to be heavy-tailed. The off periods were either “active off,” when a user is inspecting the Web browser but not transmitting data, or “inactive off,” when the user is not using the Web browser. Active off periods could be fit with a Weibull probability distribution, while inactive off periods could be fit by a Pareto probability distribution. The Pareto distribution is heavy-tailed. However, the self-similarity in Web traffic was attributed mainly to the heavy-tailed on periods (or essentially, the heavy-tailed distribution of Web files).

A study of 1900 Web-browser clients also characterized Web traffic with an on/off model (Choi and Limb 1999). Off periods include the user viewing the browser or doing something else. Off periods were fit with a Weibull probability distribution, consistent with earlier studies. The on period again represents a retrieved Web page, but the model was refined with a more detailed view of a Web page, as shown in Figure 10. A Web page consists of a main object, which is an HTML document, and multiple in-line objects that are linked to the main object. Both main object sizes and in-line object sizes were fit with (different) log-normal probability distributions. The number of in-line objects associated with the same main object was found to follow a gamma probability distribution. In the same Web page, the intervals between the start times of consecutive in-line objects was fit with a gamma probability distribution.

It has been argued that TCP flow models are more natural for Web traffic than are “page-based” models (Cao et al. 2004). Requests for TCP connections originate from a set of Web clients and go to one of multiple Web servers. A model parameter is the random time between new TCP connection requests. A TCP connection is held between a client and server for the duration of a random number of request/response transactions. Additional model parameters include sizes of request messages, server response delay, sizes of response messages, and delay until the next request message. Statistics for these model parameters were collected from days of traffic traces on two high-speed Internet access links.

Another study examined 24 hours of flow records from NetFlow-capable routers in the Abilene backbone network (Meiss, Menczer, and Vespignani 2005). Web traffic composed 4% (319 million flows) of the total observed traffic. The Web traffic flows were mapped to a graph of 18 million nodes (Web clients and servers) and 68 million links (flows between client/server pairs). The weight assigned to a link reflects the aggregate amount of data

Figure 10: On/off model with Web page consisting of a main object linked to multiple in-line objects

between the nodes. The traffic study examined the probability distribution for number of servers contacted by a client, number of clients handled by a server, amount of data sent by a client, and amount of downloads handled by a server. One of the observations is that both client and server behaviors vary extremely widely, and therefore a “typical” client or server behavior is hard to characterize.

Peer-to-Peer Traffic

Peer-to-peer (P2P) traffic is often compared with Web traffic because P2P applications work in the opposite way from client/server applications, at least in theory. In actuality, P2P applications may use servers. P2P applications consist of a signaling scheme to query and search for file locations, and a data-transfer scheme to exchange data files. Whereas the data transfer is typically between peer and peer, sometimes the signaling is done in a client/server way (e.g., the original Napster kept a centralized index).

Since P2P applications have emerged in only the past few years, there are few traffic studies to date. Studies have understandably focused more on collecting statistics than on the harder problem of stochastic modeling. One study examined the statistics of traffic on a university campus network (Saroiu et al. 2002). The observed P2P applications were Kazaa and Gnutella. The bulk of P2P traffic was AVI (audio video interleaved) and MPEG video, and a small portion was MP3 audio. With this mix of traffic, the average P2P file was about 4 MB, three orders of magnitude larger than the average Web document. A significant portion of P2P was dominated by a few very large objects (around 700 MB) accessed ten to twenty times. In other words, a small number of P2P hosts are responsible for consuming a large portion of the total network bandwidth.

Another study collected P2P traffic traces from NetFlow-capable routers in an ISP backbone network (Sen and Wang 2004). The observed P2P applications were Gnutella, Kazaa, Grokster, Morpheus, and DirectConnect. Again, an extreme skew in the traffic was observed; a small number of P2P hosts (called “heavy hitters”) accounted for much of the total traffic. The flow interarrival times, defined as the time between the host finishing one flow and then starting another flow, were found to be clustered at 1, 60, and 500 seconds. The very short (1 second) interarrival time could be the result of programmed sequential downloading of multiple files. The reason for the 60- and 500-second interarrival times was not clear.

Video

The literature on video-traffic modeling is vast because the problem is very challenging. The characteristics of compressed video can vary greatly depending on the type of video, which determines the amount of motion (from low-motion videoconferencing to high-motion broadcast video) and frequency of scene changes, and the specific intraframe and interframe video coding algorithms. Generally, interframe encoding takes the differences between consecutive frames, compensating for the estimated motion of objects in the scene. Hence, more motion means that the video traffic rate is more dynamic, and more

frequent scene changes manifest as more “spikes” in the traffic rate.

Although many video coding algorithms exist, the greatest interest has been in the MPEG standards. Approved in 1992, MPEG-1 video coding was designed for reasonable-quality video at low bit rates. MPEG-2 video encoding at higher bit rates (such as DVDs) was approved in 1994. MPEG-4 approved in 1998 is highly efficient video coding for broadcast and interactive environments. In 2003, a more efficient coding method was approved jointly by the Telecommunication Standardization Sector of the International Telecommunication Union (ITU-T) as H.264 and MPEG as MPEG-4 Part 10 (also known as “advanced video coding”).

Video source rates are typically measured frame by frame (which are usually 1/30 second apart). That is, X_n represents the bit rate of the n th video frame. Video source models address at least these statistical characteristics: the probability distribution for the amount of data per frame, the correlation structure between frames, times between scene changes, and the probability distribution for the length of video files.

Because of the wide range of video characteristics and available video coding techniques, it has seemed impossible to find a single universal video traffic model (Heyman and Lakshman 1996). The best model varies from video file to video file. A summary of research findings:

- The amount of data per frame have been fit to log normal, gamma, and Pareto probability distributions or combinations of them.
- The autocorrelation function for low-motion video is roughly exponential (Maglaris et al. 1988). The autocorrelation function for broadcast video is more complicated, exhibiting both short-range dependence at short lags and long-range dependence at much longer lags (Ma and Ji 2001). Time-series, Markov-modulated, and wavelet models are popular for capturing the autocorrelation structure (Dai and Loguinov 2005).
- The lengths of scenes usually follow Pareto, Weibull, or gamma probability distributions.
- The amounts of data in scene change frames are uncorrelated and follow Weibull, gamma, or unknown probability distributions.
- The lengths of streaming video found on the Web appear to have a long-tailed Pareto probability distribution (Li et al. 2005).

ACCESS-REGULATED SOURCES

Traffic sources cannot typically transmit data without any constraints. To be more realistic, traffic models must taking the limiting factors into account. For one thing, networks can regulate or “police” the rate of source traffic at the user-network interface in order to prevent congestion. Access policing is more common in networks in which connections are established by a signaling protocol. Signaling messages inform the network about traffic characteristics (e.g., peak rate, mean rate) and request a QoS. If a connection is accepted, the QoS is guaranteed as long as source traffic conforms to the given traffic

parameters. A policer enforces conformance to given traffic parameters by limiting the source traffic as necessary.

Leaky-Bucket-Regulated Sources

The simplest policer enforces a peak rate defined by the shortest allowable interarrival time between two consecutive packets. If packets are arriving too closely in time, the second packet is nonconforming and therefore discarded. However, a policer with more tolerance for minor deviations from the peak rate is preferred.

The leaky-bucket algorithm is typically used for access policing because its enforcement is flexible, depending on the adjustment of two parameters: the bucket size B and a leak rate R . Packets are conforming and admitted into the network if they can increment the bucket contents by their payload size without overflowing. The contents of the bucket are emptied at the leak rate R . The leak rate R is the long-term average rate allowed. A larger bucket size allows greater variations from the rate R . A burst at a rate higher than R can still be conforming as long as the burst is not long enough to overflow the bucket. Hence, the maximum burst length b is directly related to the bucket size.

The maximum amount of traffic allowed by a leaky-bucket policer in an interval $(0, t)$ is represented by the deterministic (σ, ρ) calculus (Cruz 1991). The allowable traffic is deterministically bounded by

$$\int_0^t X(s)ds \leq \sigma + \rho t \quad (14)$$

where $\sigma > 0$, $\rho > 0$. From equation (14), it is clear that ρ is the long-term average rate, while σ is an allowable burst size.

Bounding-Interval-Length-Dependent Model

The deterministic bounding-interval-length-dependent (D-BIND) model characterizes traffic sources by multiple rate-interval pairs (R_k, I_k) . R_k is the worst-case rate measured over every interval of length I_k . For practical applications, only a limited number of pairs would be used to characterize a source (Knightly and Zhang 1997).

S-BIND is a stochastic version in which a traffic source is similarly characterized by multiple pairs. In this case, R_k is a random variable that is stochastically larger than the rate over any interval of length I_k . Suppose r_k is the traffic rate in interval I_k , then $\Pr(R_k > x) \geq \Pr(r_k > x)$.

CONGESTION-DEPENDENT FLOWS

Traffic sources may be limited by access control or the level of network congestion. Some protocols limit the sending rates of hosts by means of sliding windows or closed-loop rate control. Clearly, traffic models must take such protocols into account in order to be realistic. Here we focus on TCP because TCP traffic constitutes the vast majority of Internet traffic. TCP uses a congestion-avoidance algorithm that infers the level of network congestion and adjusts the transmission rate of hosts accordingly. Even

other protocols should be “TCP friendly,” meaning that they interact fairly with TCP flows.

TCP Flows with Congestion Avoidance

TCP senders follow a self-limiting congestion-avoidance algorithm that adjusts the size of a congestion window according to the inferred level of congestion in the network. The congestion window is adjusted by so-called additive increase multiplicative decrease (AIMD). In the absence of congestion when packets are acknowledged before their retransmission time-out, the congestion window is allowed to expand linearly. If a retransmission timer expires, TCP assumes that the packet was lost and infers that the network is entering congestion. The congestion window is collapsed by a factor of a half. Thus, TCP flows generally have the classic “sawtooth” shape (Firoiu and Borden 2000; Paxson 1994).

Accurate models of TCP dynamics are important because of TCP’s dominant effect on Internet performance and stability. Hence, many studies have attempted to model TCP dynamics (Mathis et al. 1997; Padhye et al. 2000; Barakat et al. 2003.) Simple equations for the average throughput exist, but the problem of characterizing the time-varying flow dynamics is generally difficult because of interdependence on many parameters, such as the TCP connection path length, round-trip time, probability of packet loss, link bandwidths, buffer sizes, packet sizes, and number of interacting TCP connections.

TCP Flows with Active Queue Management

The TCP congestion-avoidance algorithm has an unfortunate behavior whereby TCP flows tend to become synchronized. When a buffer overflows, it takes some time for TCP sources to detect a packet loss. In the meantime, the buffer continues to overflow, and packets will be discarded from multiple TCP flows. Thus, many TCP sources will detect packet loss and slow down at the same time. The synchronization phenomenon causes underutilization and large queues.

Active queue-management schemes, mainly random early detection (RED) and its many variants, eliminate the synchronization phenomenon and thereby try to achieve better utilization and shorter queue lengths (Floyd and Jacobson 1993; Firoiu and Borden 2000). Instead of waiting for the buffer to overflow, RED drops a packet randomly, with the goal of losing packets from multiple TCP flows at different times. Thus, TCP flows are unsynchronized, and their aggregate rate is smoother than before. From a queuing theory viewpoint, smooth traffic achieves the best utilization and shortest queue.

Active queue management has stimulated a number of control-theory approaches to understanding the stability, fairness issues, and flow dynamics (Tan et al. 2006; Srikant 2004).

CONCLUSION

Proper network design requires an understanding of the source traffic entering the network. Many continuous-time and discrete-time traffic models have been developed

based on traffic-measurement data. The choice of traffic models involves at least two major considerations. The first is accuracy. Accurate traffic models should include not only source behavior but also possible policing or congestion avoidance. The second consideration is ease of queuing analysis. Traffic models are useful only if network performance can be evaluated. It is always possible to evaluate network performance via computer simulations, but analysis is preferred whenever analysis is tractable.

GLOSSARY

Access Policing: Regulation of ingress traffic at the user-network interface.

Active Queue Management (AQM): Intelligent buffer management strategies, mainly random early detection (RED) and its variants, enabling traffic sources to respond to congestion before buffers overflow.

Autoregressive Moving Average (ARMA): A general type of time-series model, including linear dependence on previous data samples and linear dependence on noise samples.

Burstiness: A measure of the variability of a traffic source rate.

Fluid Model: A view of data traffic ignoring the discrete nature of packets.

Fractional Brownian Motion (FBM): A long-range dependent Gaussian process with stationary increments including Brownian motion as a special case.

Leaky Bucket: A flexible algorithm for policing a specific traffic rate with an adjustable tolerance for deviation from that rate.

Long-Range Dependence (LRD): A property of stochastic processes with autocorrelation functions that decay more slowly than exponentially.

Markov Modulated Poisson Process (MMPP): A Poisson process in which the arrival rate varies according to a continuous-time Markov chain.

On/Off Model: A stochastic process with alternating active and idle states.

Poisson Process: A point process with interarrival times that are independent and identically distributed exponential random variables.

Quality of Service (QoS): The end-to-end network performance defined from the perspective of a specific user's connection.

Self-Similarity: A property of stochastic processes that preserve statistical characteristics over different time scales.

Time Series: A discrete-time stochastic process usually considered to represent measurements of a random phenomenon sampled at regularly spaced times.

Transmission Control Protocol (TCP): A transport layer protocol used over IP to ensure reliable data delivery between hosts.

INTRODUCTION

Although an analogy between computer networks and automobile highways is simplistic, the view of networks as a type of infrastructure points out the need for traffic control. Highways have a limited capacity, which can be exceeded when many people want to travel at the same time. Vehicles begin to slow down and back up in a congested area. The backup spreads if traffic approaches the congested area faster than traffic can leave it. Similarly, computer networks are designed to handle a certain amount of traffic with an acceptable level of network performance. Network performance will deteriorate if the offered traffic exceeds the given network capacity.

Packets will suffer long queuing delays at congested nodes and possibly packet loss if buffers overflow.

Traffic management refers to the set of traffic controls within the network that regulate traffic flows for the purpose of maintaining the usability of the network during conditions of congestion. Traffic management has multiple goals. First, it attempts to distinguish different types of traffic and handle each type in the appropriate way. For example, real-time traffic is forwarded with minimal delay, while best-effort traffic can afford to wait longer for any unused bandwidth. Second, traffic management responds to the onset of congestion. TCP is an example of a protocol that adapts the rate of TCP sources to avoid serious congestion. Third, traffic management seeks to maintain an acceptable level of network performance under heavy traffic conditions. The primary means of protection are admission control and access regulation (or policing), which limit the rate of traffic entering the network. By restricting the total amount of carried traffic, congestion

will be avoided, and acceptable network performance will thus be sustained at the expense of blocking some amount of ingress traffic.

Quality of Service

Quality of service (QoS) is closely related to network performance, but QoS metrics are oriented toward a user's end-to-end experience (Gozdecki, Jajszczyk, and Stankiewicz 2003). Network performance is measured mainly from the network provider's viewpoint. Network performance metrics are defined to provide a meaningful portrait of network behavior to the network provider or network manager. Metrics can include end-to-end or hop-by-hop performance, and may be aggregated over the entire user population. Examples of network performance metrics may be average end-to-end packet delay or fraction of packets lost per hop observed over an interval of time. Although interesting to the network provider, these metrics do not mean that a particular user will see this network performance. Therefore, they are not that meaningful to users concerned with their application's requirements.

In contrast, QoS is the end-to-end network performance seen from the viewpoint of a user's particular connection. QoS parameters are defined to quantify the performance needed and experienced by a user's application. For example, a real-time application might require QoS guarantees such as an end-to-end packet delay of 10 msec and packet loss rate of 10^{-6} . The user would be assured that his or her application would see this level of performance. At the same time, a different user may require a different QoS from the same network. Ultimately, a certain amount of subjectivity is involved. A user will judge the QoS

provided by the network according to how well his or her application seems to work.

QoS may not necessarily be quantified in specific terms. “Hard” QoS may refer to specific guarantees, whereas “soft” QoS involves specific parameters but no guarantees. An example of hard QoS is a guarantee that no more than 1% of packets will experience a delay of 100 msec. Hard QoS can be verifiable by measurements of the QoS parameters. Soft QoS may specify target QoS parameters but offers no guarantees that the QoS will be met; hence soft QoS is not verifiable by measurements. Soft QoS is often defined for one service relative to another service. An example is a high-priority service that is guaranteed to always have a shorter average packet delay than a low-priority service, but there are no absolute guarantees for either high- or low-priority service.

ATM has taken the approach of hard QoS guarantees. Table 1 lists the ATM definitions of QoS parameters (ATM Forum 1996). Although guarantees are offered on all QoS parameters, not all guarantees need to be specified explicitly. For example, it is assumed implicitly that the bit error rate in ATM (asynchronous transfer mode) networks will be very low, so the cell error ratio will be very low and therefore unnecessary to negotiate explicitly. Likewise, misinserted cells are considered to be very rare and negligible under normal operating conditions. The QoS parameters that are explicitly negotiated are mainly the cell loss ratio, cell transfer delay, and cell delay variation.

Similar QoS definitions have been standardized for IP (Internet protocol) networks (Seitz 2003). In the late 1990s, the IETF (Internet Engineering Task Force) IP Performance Metrics (IPPM) Working Group documented a set of QoS metrics for IP networks including one-way packet delay, round-trip packet delay, and one-way packet loss. More recently, the ITU-T (International Telecommunication Union, Telecommunication Standardization Sector) has standardized the set of IP performance metrics listed in Table 2 (ITU-T 1999).

Service-Level Agreements

Expectations for QoS may be specified in the form of a service-level agreement (SLA) between users and their network provider or between two network providers (Verma 2004). An SLA formally spells out expectations about the level of service in a way that allows monitoring and verification. SLAs often include terms for billing and financial compensation in case the received service level falls short of expectations. Hence, SLAs are legal contracts that must include clearly specified QoS metrics—typically availability, packet delay, jitter, packet loss, and throughput (Park, Baek, and Hong 2001). In common practice, SLAs are viewed more as insurance for unexpected lapses in network performance than as absolute guarantees, because of the practical difficulties of measuring and verifying QoS metrics.

Table 1: ATM Definitions of QoS Parameters

Aspect	Parameter	Definition
Accuracy	Cell error ratio	Fraction of cells delivered with bit errors
	Severely errored cell block ratio	Fraction of N -cell blocks delivered with M or more errored cells
	Cell misinsertion rate	Rate of appearance of misdirected cells from a different connection
Dependability	Cell loss ratio	Fraction of cells not delivered
Speed	Cell transfer delay	Maximum delay in delivering cells measured by p -percentile
	Cell delay variation (jitter)	Range between maximum and minimum cell delays, or deviation of cell delivery times from a reference pattern

Table 2: QoS Metrics for IP Networks

Aspect	Parameter	Definition
Accuracy	IP packet error ratio	Fraction of packets delivered with bit errors
	Spurious IP packet rate	Rate of appearance of misdirected packets at a network egress
Dependability	IP packet loss ratio	Fraction of packets not delivered
Speed	IP packet transfer delay	Mean or maximum delay in delivering packets
	IP packet delay variation (jitter)	Deviation in packet transfer delays from a reference packet transfer delay

SLAs typically share a few common elements: criteria to be used for measuring service levels; a method for reporting outages and service failures; timeframe for the network provider to respond to identified failures; a method for escalating network problems; and procedures for enforcement and compensation for failure to meet SLA goals.

SLAs are typically limited to a single provider network. However, routes through the Internet can cross multiple networks. SLAs can be negotiated between network providers, but the issue becomes how to guarantee the end-to-end QoS to users (Pongpaibool and Kim 2003).

General Principles

Traffic management is a difficult problem because it fundamentally involves a balance between conflicting objectives: statistical sharing versus isolation. At one extreme, statistical sharing of network resources without reservations is desirable to achieve a high efficiency. But since demand can exhaust resources, it is difficult (if not impossible) to guarantee QoS without reservations. At the other extreme, it is well known that QoS can be guaranteed by reserving resources for each traffic flow. Reservations isolate resources for each traffic flow so that flows do not have to compete for resources.

Another general principle is that traffic controls can be exercised simultaneously at various levels. At the node level, routers and switches are responsible for packet scheduling and selective packet discarding. Ingress nodes can perform access policing. Nodes may be capable of explicit congestion notification. At the network level, the network makes admission control decisions to accept or block new packet flows. At the higher level, transport or application layer protocols can be adaptive to the congestion level in the network.

Traffic control methods can be classified as preventive or reactive. Reactive methods are activated to ameliorate congestion after it is detected. For example, TCP reacts to congestion by reducing TCP source rates. A general principle is that prevention of congestion is preferred to reacting to congestion. If congestion occurs, packets will be lost, and it takes time to clear the queues in congested nodes. Preventive methods such as explicit congestion notification are preferred because congestion and packet loss may be avoided.

Overview of Methods

In practice, networks generally depend on a variety of traffic controls used at different points in the networks (El-Gendy, Bose, and Shin 2003). The main preventive traffic control is admission control. Admission control gives the network an opportunity to make a decision whether to accept or reject a new traffic flow before the flow begins. Admission control can be quite effective in protecting the network from congestion by blocking new traffic flows at the network ingress (Firoiu et al. 2002). Typically, admission control relies on a signaling protocol that allows applications to explicitly request a QoS or service class. Information about the new traffic flow (e.g., peak rate, average rate, burstiness) must be provided to the network at the same time so that sufficient resources can

be allocated. A signaling protocol is not absolutely necessary if the required QoS can be inferred implicitly from knowledge about the traffic. For example, the telephone network uses admission control. Since every telephone call requires the same QoS, the required QoS does not have to be signaled explicitly.

Access or ingress policing is another preventive traffic control that typically accompanies admission control. Since admission control decisions are based on information about the accepted new traffic, it is important that source traffic conforms to the given parameters because excessive traffic could degrade network performance to the point of violating QoS guarantees. The most widely used algorithm for access policing is the leaky bucket. The leaky-bucket algorithm is simple to implement with counters, and allows adjustable tolerance for bursty traffic sources. For conforming traffic, the access policing should be invisible and make no difference. For excess traffic, three actions are possible: the excess traffic is admitted; it is admitted but marked with lower priority; or it is discarded immediately.

Packet scheduling is an essential traffic control because it recognizes that packets have different forwarding requirements. Packet scheduling should recognize different service priorities and give preferential treatment to packets with more stringent delay requirements.

Buffer management is a problem complementary to packet scheduling. Whereas packet scheduling deals with the order of packets to depart from a buffer, buffer management dictates how incoming packets should fill up limited buffer space. Buffer management should recognize different loss priorities and selectively discard packets of lower loss priority. In a way, loss priorities may be viewed as priorities related to space, while service priorities are related to time. In addition to simple loss priorities, packets may be discarded in coordination with higher-layer protocols. For example, random early detection (RED) is a random packet discarding strategy that takes advantage of the congestion-control algorithm in TCP to improve network throughput and stability (Floyd and Jacobson 1993).

Instead of simply discarding packets during congestion, it is better to avoid congestion entirely if possible. Congestion might be avoided by inferring the state of congestion in the network by watching for long packet delays and packet losses. This does not require the network to provide any congestion information. However, the most effective way to avoid congestion is explicit congestion notification by the network. Protocols such as ATM and frame relay allow switches to mark packets when congestion appears to be imminent. Traffic sources are given enough advance warning to slow down and prevent congestion. This so-called closed loop control works only for some adaptable applications that can adjust their transmission rate dynamically (in contrast, admission control is open loop control because sources are not controlled by feedback after they are accepted).

ADMISSION CONTROL

Admission control is one of the most effective means of congestion control. The objective is to prevent congestion

by blocking new packet flows before the flow begins. If a new flow is accepted, the network is explicitly or implicitly agreeing to provide the required QoS for the duration of the flow. This agreement is explicit if the admission control is carried out with a signaling protocol.

Many approaches to admission control can be found in the literature (Firoiu et al. 2002). As shown in Figure 1, approaches can be classified according to where the acceptance decision is made: hop-by-hop, end-point or edge router, or centralized bandwidth broker (BB). Hop-by-hop admission control follows the traditional approach of telecommunications networks. A signaling message requesting resources attempts to find a path through the network. Each router or switch along the path has an opportunity to accept and forward the request or to reject and block the request. Although this is a natural approach, the complexity required for routers limits the scalability to large networks.

The second approach leaves the admission decision to the source end point (host) or an edge (ingress or egress) router (Elek, Karlsson, and Ronngre 2000). The decision can be based on data collected passively (without any extra effort) or actively by special probe packets. This approach simplifies the role of the core network, resulting in better scalability.

The third approach is also aimed at better scalability. Admission into each network domain is controlled by a centralized bandwidth broker (Zhang et al. 2000). The available resources of the domain are monitored by the BB, which makes all admission decisions and keeps track of accepted traffic flows. The BB concept has two potential advantages. It keeps the core network stateless

for scalability. Also, it can make network-wide optimal resource allocation decisions.

In order to make an acceptance or rejection decision, the network must estimate the amount of bandwidth and buffer resources needed for a new traffic flow. The required resources are compared with the available resources. The network also estimates the hypothetical impact of the new traffic flow on the current network performance. There must be assurance that the new flow will not cause the QoS for current traffic flows to fall below acceptable levels.

Approaches for admission control can be alternatively classified by how the decision is made: deterministic, stochastic, or measurement-based (Perros and Elsayed 1996). Deterministic approaches use worst-case bounds. In contrast, stochastic approaches assume statistical characteristics of the traffic for more accurate estimation of required resources. However, the accuracy of stochastic approaches depends heavily on the choice of traffic models. Traffic modeling is a difficult problem because of the dynamic nature of network traffic. Measurement-based approaches attempt to avoid the modeling problem by using measurements of the actual traffic instead of assumed traffic models.

Hop-by-Hop Admission Control

As in traditional telecommunications networks, a signaling message is sent along a path to request resources. The signaling message carries information needed for routers and switches along the path to make decisions about whether sufficient resources are available. If a router or

Figure 1: Hop-by-hop admission; (b) end-point admission; (c) centralized bandwidth broker

Figure 2: RSVP messages

switch has sufficient resources, it forwards the request to the next hop. If insufficient resources are available, it drops the request and notifies the source host by a “reject” signaling message.

RSVP (resource reservation protocol) is a well-known signaling protocol for IP networks capable of unicast or multicast reservations (Braden et al. 1997). In the basic reservation setup, a source sends an RSVP PATH message that is forwarded by each router, according to its routing table, until it reaches the destination, as shown in Figure 2. The most important element is a TSpec object that provides information about the source traffic characteristics. Traffic characteristics in the TSpec object are specified in token bucket parameters: token rate, token bucket size, peak rate, minimum policed unit, and maximum packet size.

The RSVP RESV message is returned from the destination to the source to request resources along the path traversed by the PATH message. In addition to a TSpec object, the RESV message can contain a controlled load or guaranteed load flow specification. Controlled load and guaranteed services are part of the IETF Integrated Services (IntServ) framework (Braden, Clark, and Shenker 1994). Controlled load service is intended for real-time applications that can tolerate a limited amount of packet loss and excessive packet delay. It can be viewed as “better than best-effort” and equivalent to QoS seen from an unloaded network. The controlled load flow specification in the RESV message consists of the token bucket parameters as in the TSpec object. Guaranteed service provides “hard” and measurable QoS guarantees in terms of throughput and maximum packet delay. The controlled load flow specification in the RESV message consists of token bucket parameters and an RSpec object, which includes a rate and a delay slack (delay variation) term.

RSVP suffers from two serious drawbacks: complexity and scalability (El-Gendy et al. 2003). Routers must be programmed to understand the signaling protocol and perform packet classification, packet scheduling, and admission control. The scalability problem is caused by the need for traditionally stateless routers to keep state information for each flow. RSVP uses soft state, meaning that reservation states are automatically deleted if not refreshed after some time. However, it is clear that the number of flows in the Internet will only be increasing over time, necessitating more state information to be maintained by RSVP-capable routers.

End-Point/Edge Admission Control

Hop-by-hop admission control suffers from two drawbacks: the need for a signaling protocol and the need for

all routers or switches to keep track of flow reservations. An alternative idea is that the source host could probe the network to determine whether it can accommodate the new flow (Elek et al. 2000). For example, the source host (or ingress edge router) could inject a stream of probe packets at the same rate of the new flow and measure the packet delay and loss rate. This is a direct measurement of whether the new flow can be accommodated or not. The probe test may work better if routers along the path can mark the packets with congestion information (Gibbens and Key, 2001; Ganesh et al. 2006).

The probing method has been proposed for voice over IP (VoIP) calls (Mase 2004). It is claimed that the probing method over controls call admission, so the method is modified so that call requests failing the probe test can be accepted with some adjustable probability.

Egress admission control places the decision at the egress edge router (Cetinkaya, Kanodia, and Knightly 2001). The network is viewed as a black box, and the egress router just monitors data flows to infer the internal state of the network. The service capacity between ingress and egress end-points is estimated. If the new flow combined with the existing flows can be accommodated by the service capacity, the new flow is admitted. The advantage of the method is no need for probe packets.

Bandwidth Brokers

In differentiated services (Diffserv), the core routers are stateless for scalability, and complex traffic controls are pushed to the edge routers. Although ingress or egress routers could take responsibility for admission control, another idea is to centralize admission control in a BB entity (Nichols, Jacobson, and Zhang 1999). The BB keeps track of allocated and available resources in a Diffserv domain, makes all admission decisions, and configures the packet classifiers and traffic conditioners at the edges of the Diffserv domain to regulate incoming traffic.

The major advantage is scalability, because core routers are concerned only with packet forwarding. Another advantage is the network-wide view of the BB. This network-wide view should enable the BB to make optimal resource allocation decisions (e.g., balance traffic across the network). However, there may be a performance issue because the BB keeps all state information and makes all decisions. As a Diffserv domain grows larger, the BB could become a processing and communications bottleneck. It is also a single point of failure. To alleviate this problem, a hierarchy of BBs may be possible.

It is envisioned that bandwidth brokers in adjacent Diffserv domains could negotiate with each other to establish

end-to-end services across multiple domains. However, an inter-BB protocol does not currently exist.

Deterministic Bounds

The deterministic approach to admission control assumes the worst-case traffic scenario, which is the peak rate for each traffic flow. A new flow is accepted if the sum of the peak rates for all flows is less than the physical capacity. It is obvious that traffic flows may be well below the peak rates in actuality, leading to considerable underutilization of capacity. However, this approach has appealing advantages. First, admission control is a simple decision. Second, the peak rate is always known, so the physical capacity will never be exceeded and QoS can be guaranteed.

Stochastic Bounds

For bursty traffic flows with random time-varying rates, it makes sense to allocate bandwidth less than the peak rates and assume that some capacity can be saved by statistical multiplexing (Firoiu et al. 2002). When a large number of flows are multiplexed, it is unlikely that all flows will be bursting at their peak rates simultaneously. Hence, an amount of bandwidth somewhat less than the sum of peak rates is needed.

The savings from statistical multiplexing is usually estimated from a finite-size queuing model. The queue represents the buffer in the switch or router making the admission control decision. The input to the queue is a stochastic process representing the random behavior of traffic sources. A number of traffic models have been proposed in the literature based on studies of historical traffic measurements (Michiel and Laevens 1997). Common traffic models include the Poisson process, interrupted Poisson process, simple on-off model, Markov modulated processes (such as the Markov modulated Poisson process), and ARMA (autoregressive moving averages) time series (Adas 1997). Due to the challenges of solving complex queueing systems, another popular model is the stochastic fluid buffer, where the input traffic is viewed as Markov modulated fluid flow instead of discrete packets. In any case, the delay through the queue and probability of buffer overflow are calculated for the hypothetical traffic. If the delay and buffer overflow probability meet the desired QoS, then the new traffic flow is accepted.

A popular alternative approach is to calculate the equivalent capacity for each traffic flow (Kelly 1996). The appeal of equivalent capacity is a simple admission control decision. The equivalent capacity for the total traffic is compared with the available physical capacity. The equivalent capacity for a source is derived by imagining the source as input into a finite queue. The equivalent capacity is the service rate resulting in the target buffer overflow probability. There are different expressions for equivalent capacity, depending on the source traffic characteristics. The equivalent capacity for multiple sources is derived similarly, whereby the aggregate traffic from the sources is the input into a finite queue. Generally, the equivalent capacity for multiple sources will be less than the sum of their individual equivalent capacities, due to the savings from statistical multiplexing.

Measurement-Based Admission Control

The accuracy of statistical admission control depends on correct assumptions for the source traffic models. Measurement-based admission control is motivated by the difficulty of choosing a traffic model for a new packet flow based on limited information. A traffic source may provide descriptive parameters but they may be inaccurate or uncertain. Measurement-based admission control avoids the need to assume a traffic model by characterizing sources by statistics measured from the actual traffic instead.

Several measurement-based methods have been proposed (Shiomoto, Yamanaka, and Takahashi 1999). The various methods all depend on measurements of the actual traffic made during a recent time window but differ in their usage of the measurements. For example, the measurements can be used to derive a marginal probability distribution for the source rates. The marginal probability distribution is then used to estimate the buffer overflow probability for a hypothetical finite queue. As a second example, the mean and variance of the source rates are measured. The effective capacity of the sources is derived from the mean and variance. As a third example, a frequency analysis of the source rates reveals the low-frequency and high-frequency components. Queuing is considered to accommodate high-frequency variations, and admission control is based on the low-frequency components.

ACCESS CONTROL

Access control, or *policing*, refers to regulation of ingress traffic at the user-network interface. There are reasons for regulating traffic at the network edge and not internally within the network. At the network boundary, excessive traffic can be blocked before consuming any network resources. Moreover, it is natural to verify conformance of the traffic as close to the source as possible before the traffic shape is affected by other packet flows. Finally, individual packet flows at the network edge are slower than multiplexed flows in the core network.

Traffic Contracts

When an admission control decision is made, that decision is based on traffic descriptors and QoS parameters provided by traffic sources. If the network admits a packet flow, it might be said that the user and network have agreed on a traffic contract. Unlike SLAs, traffic contracts are a misnomer because they are not legal agreements. A traffic contract is an implicit understanding between the network and sources that both sides are cooperating in admission control. Sources are obligated to conform to the traffic descriptors that they provided for the admission decision. Excessive traffic will consume more network resources and deteriorate the QoS seen by all users. In accepting a new flow, the network is obligated to provide and sustain the requested QoS.

Traffic Classification

Packets must be classified to determine their QoS requirements or which flow they belong to. In the Intserv

framework, reservations are made for individual flows. Packets belonging to the same flow can be identified by these IP header fields: source IP address, destination IP address, source port number, destination port number, and protocol.

Packet classification is difficult for at least two reasons. First, routers must process terabytes of packets per second (Chao 2002). Thus, packet classification must be done very quickly and efficiently (Yu, Katz, and Lakshman 2005). Second, there may be an enormous number of flows going through a router. Classification of a packet to a particular flow essentially involves a table search, but the table could be enormous. Packet classification is an ongoing research problem that is central to router design (Van Lunteren and Engbersen 2003; Wang et al. 2004; Baboescu and Varghese 2005).

In the Diffserv framework, packets must be classified at the ingress to the Diffserv network such that an appropriate Diffserv codepoint (DSCP) can be assigned (Carpenter and Nichols 2002). The DSCP is encoded in the first six bits of the type of service (ToS) field in the IPv4 packet header. The DSCP identifies the per-hop behavior (PHB) to be applied to the packet.

Traffic Regulation

The rate of traffic entering the network can be regulated as a means of enforcing the traffic contract. Since admission control decisions are based on traffic parameters given for a packet flow, it is important that flows do not exceed their stated parameters because excessive traffic would deteriorate the network performance seen by all users.

The goal of traffic regulation is to differentiate between conforming and nonconforming packets (according to the traffic contract). Conforming packets should be allowed immediate entrance into the network as if the traffic policer was transparent. Nonconforming packets may be discarded immediately or allowed entrance with some kind of packet marking. The former is preferred if the network load is heavy, then it would be better to discard the nonconforming packets to avoid any wasted use of network resources. The idea behind packet marking is that the purpose of the network is to carry packets. If the network load is light, it does no harm to carry nonconforming traffic. If congestion is encountered anywhere, the marked packets can be discarded first.

In the Diffserv framework, packets may also be classified into flows that are subject to policing and marking according to a traffic conditioning agreement (TCA). The TCA includes traffic characteristics (such as token bucket parameters) and performance metrics (delay, throughput) as actions required for dropping out-of-profile packets (Longsong, Tianji, and Lo 2000). Out-of-profile packets are nonconforming packets, and they are either dropped or marked with a lower priority level.

Traffic Shaping

Traffic shaping can be done at the source prior to entrance into the network or within the network. Traffic shaping at the source is a means of self-regulation in order to

ensure conformance to the traffic contract. Conformance is desirable, to minimize the amount of traffic discarded at the network ingress.

Traffic shaping within the network is not concerned with a traffic contract. The idea is that smooth traffic will cause smaller queues and hence incur shorter queuing delays and less delay jitter (Rexford et al. 1997). Since traffic shaping is done by buffering, some queuing delay is added by the traffic shaper, but then smooth traffic should flow more quickly along the rest of the path. Overall, network performance is improved by keeping traffic smooth (Elwalid and Mitra 1997).

Leaky-Bucket Algorithm

The leaky-bucket algorithm is widely used for access control. There are different versions. The basic version consists of a buffer (bucket) of size B and a leak rate R , as shown in Figure 3a. Packets are conforming if they can join the buffer without overflowing. The contents of the buffer are emptied at the leak rate R . A larger bucket size allows greater variations from the rate R . A burst at a higher rate can still be conforming as long as the burst is not long enough to overflow the bucket. Hence, the maximum burst length is directly related to the bucket size.

One variation is the token bucket. Tokens at some generation rate R can collect in a bucket size of B , as shown in Figure 3b. A packet is conforming if it can find and consume a token waiting in the bucket. Again, a larger bucket allows longer bursts to be conforming.

The leaky-bucket algorithm can be easily implemented by a counter. Another advantage is the simple use of dual leaky buckets in tandem to regulate both average rate and peak rate. For example, the first leaky bucket can regulate the peak rate, and the second leaky bucket can regulate the average rate.

PACKET SCHEDULING

Packet scheduling addresses the different needs of buffered packets contending for the same link bandwidth (El-Gendy et al. 2003). Packet scheduling should take into account the QoS requirements of each packet flow.

Figure 3: (a) Leaky-bucket policer; (b) token bucket

A packet flow may require a minimum throughput, maximum end-to-end delay, or maximum packet delay jitter.

A general principle of packet scheduling is that the average waiting time for all packets does not change under different schedules. In other words, giving higher priority to transmit one packet earlier comes at the expense of making other packets wait longer. Benefits to one packet's flow penalizes other packets. Hence, fairness is another issue when packet schedules are considered (Dua and Bambos 2005).

Priorities

A simple and intuitive packet schedule gives preferential treatment according to static priorities. Each packet belongs to one of priority levels 1 to N , where priority 1 is always transmitted first, priority 2 is transmitted when there are no priority 1 packets, and so on. The priority is static in the sense that a packet's priority never changes during its lifetime.

The advantage of static priorities is straightforward implementation. Different-priority packets may be queued in separate buffers, as shown in Figure 4. The priority buffers may be implemented as physically separate buffers or a single physical buffer separated into multiple virtual buffers.

A well-known disadvantage of static priorities is the possibility of starvation of low priorities. The high priority packets can consume all of the bandwidth and prevent low priority packets from receiving service. A possible solution to the starvation problem is dynamic priorities. For example, the priority of a packet can increase with its waiting time. As a packet is waiting, it will eventually receive service, ensuring some fairness. However, dynamic priorities are much more difficult to implement than simple priorities because the waiting times must be tracked for each packet.

Round Robin

Round robin is another simple and intuitive scheduling algorithm. Each packet flow is queued in a separate buffer, and the head of line 1 is transmitted, then the head of line 2, and so on, eventually back to line 1, as shown in Figure 5. Empty queues are skipped over immediately to avoid wasting bandwidth.

Round robin is intuitively fair because each packet flow takes equal turns during a round or cycle. However, it may not be entirely fair. First, packets may be unequal in size. If the packets of one flow are long, that flow will consume more bandwidth compared to flows with shorter packets.

Figure 4: Priority buffers

Figure 5: Round-robin scheduling

Second, certain flows may naturally require more bandwidth than other flows (e.g., video versus voice).

A simple modification is weighted round robin. The packet flows are assigned weights $w_1, w_2, \dots, w_N$. A higher weight means that more packets are transmitted from that buffer in each turn. For example, if $w_1 = 2w_2$, then twice as many packets are transmitted from queue 1 than from queue 2 in each turn. Sophisticated schemes can adapt the weights per flow based on the traffic behaviors (Wang, Shen, and Shin 2001).

Fair Queueing

Fair queueing is closely related to round robin. Recall that a potential cause of unfairness in round-robin scheduling is unequal packet sizes. A logical modification is round robin on the basis of bits instead of packets. Fair queueing might be considered as an approximation to bit-by-bit round robin. It is obvious that bit-by-bit fair queueing cannot be implemented in actuality because packets must be transmitted in their entirety, not piecemeal as separate bits.

In fair queueing, the hypothetical finishing time of each packet under bit-by-bit round robin is calculated and associated with that packet (Demers, Keshav, and Shenker 1989). The next packet chosen to transmit is always the packet waiting with the earliest hypothetical finishing time.

Along the same idea, weighted fair queueing (WFQ) is a packet-by-packet approximation to bit-by-bit weighted round robin. It is so-called fair in the sense that the i th packet flow is guaranteed a fraction of bandwidth equal to at least $w_i/(w_1 + \dots + w_N)$.

As a consequence of the guaranteed bandwidth, it may be expected that if a traffic source is rate-limited, then the delay through a queuing system with WFQ would be bounded (Parekh and Gallager 1993). Suppose each traffic flow is regulated by a token bucket with bucket size B_i and token rate R_i . Furthermore, assume that WFQ is used with relative weights $w_i = R_i$ for the flows. The maximum delay experienced by the i th flow through the node will be bounded by $D_i \leq B_i/R_i$. The bounded delay is an important advantage of WFQ because it means that admission control can guarantee a maximum end-to-end packet delay.

Deadline Scheduling

A widely studied class of scheduling algorithms is based on deadlines (Conway, Maxwell, and Miller 2003). When a packet arrives at the buffer, it is assigned a deadline

d , which is the time when it should be transmitted. For example, a real-time packet might have a deadline that is a short time after its arrival time a , whereas a non-real-time packet might have a deadline much farther in the future. The finishing time f of a packet is the sum $f = a + w + x$, where w is the waiting time before starting service, and x is its service time (i.e., transmission time). If a packet is transmitted by finishing time f , the packet's lateness is $l = f - d$. A packet with positive lateness has not met its deadline, whereas a packet with negative lateness is considered early. Typically, a penalty is associated with lateness but not with earliness.

A number of optimal schedules are known, depending on the criterion to optimize. The shortest processing time (SPT) discipline takes packets in order of increasing service time. That is, the next packet to transmit is always the packet waiting with the smallest service time. The SPT schedule is known to minimize the average waiting time and minimize the average lateness (averaged over all packets).

In certain cases, the most late packet is more important than the packet of average lateness. Another well-known optimal schedule is the earliest due date (EDD) or earliest deadline first (EDF) discipline. The next packet to transmit is always the packet waiting with the earliest deadline. The EDD schedule is known to minimize the maximum lateness. Suppose the packet that is most late under any schedule has lateness $l_{\max}$. EDD is optimal in the sense that no other schedule will realize a smaller $l_{\max}$ than the EDD schedule.

BUFFER MANAGEMENT

Buffer management deals with how packets are given preferential access to limited buffer space. If packets are allowed into a full buffer, then packets already waiting in the buffer must be discarded to make space available. Hence, buffer management is also the problem of selective packet discarding (Labrador and Banerjee 1999).

Loss Priorities

In theory, packets may be marked with an explicit loss priority. ATM and frame relay are examples of protocols that include a bit in the packet header to indicate loss priority. The ATM cell header has a cell loss priority (CLP) bit, and cells with $CLP = 1$ are dropped first at congested switches. The frame relay header has a discard eligibility (DE) bit. Frames marked with $DE = 1$ are discarded before $DE = 0$ frames.

Although the ToS field in the IP packet header has a bit to maximize reliability (or presumably minimize the likelihood of dropping), the ToS field has ambiguous interpretations and has been preempted by the Diffserv codepoint. Thus, IP does not allow explicit loss priorities. However, strategies for discarding IP packets are an active area of research because packet loss affects TCP performance. These strategies are usually called "active queue management" (AQM) (Ryu, Rump, and Qiao 2003). The most important example, random early detection (RED), is discussed later in this chapter.

Push-Out Schemes

The simplest packet-discarding strategy is tail drop. When a buffer is full, arriving packets are dropped. This strategy has a potential "lock-out" problem, in which a subset of flows can monopolize the buffer space and prevent other flows from gaining access. In fact, higher-rate flows will gain more buffer space at the expense of lower-rate flows. Another drawback is that buffer congestion can continue for a long time when the traffic is TCP. TCP slows down when a dropped packet is detected by a retransmission time-out. A packet at the queue tail was transmitted later than a packet at the head of the queue. Therefore, a packet dropped from the tail will time-out at a later time than a packet dropped from the head. TCP sources will continue to transmit for a longer time before slowing down.

A third drawback is that simple tail drop does not recognize that packets have different loss priorities. If an arriving packet has high loss priority, it should be able to access the buffer space by discarding a packet of lower priority already in the buffer. The packet of lower priority is said to be pushed out (Roy and Panwar 2002). There are basically three push-out strategies: dropping low-priority packets near the head first, near the tail first, or randomly from anywhere in the buffer. For TCP traffic, dropping from the head of the queue works better (Lakshman, Neidhardt, and Ott 1996). In general though, optimal push-out schemes are not known (Sharma and Viniotis 1999).

Random Early Detection

The simple tail-drop strategy causes the undesirable phenomenon of global synchronization of TCP flows. TCP sources search for the proper sending rate by essentially increasing the rate until a dropped packet is detected by a retransmission time-out. The details of the TCP congestion-avoidance algorithm are described below. When a buffer overflows, it takes some time for TCP sources to detect a packet loss. In the meantime, the buffer continues to overflow, and packets will be discarded from multiple TCP flows. Thus, many TCP sources will detect packet loss and slow down at the same time. Even if the TCP sources were initially out of phase, they will become synchronized. The synchronization phenomenon causes underutilization and large queues. Underutilization occurs when all sources slow down (in "slow start"), then large queues are accumulated when all sources simultaneously increase their transmission rates.

RED eliminates the synchronization phenomenon and thereby achieves better utilization and smaller queues (Floyd and Jacobson 1993). A great advantage is that RED can be implemented as a buffer-management strategy with no change to the existing TCP protocol. Instead of waiting for the buffer to overflow, RED drops a packet randomly with the goal of losing packets from multiple TCP flows at different times. Therefore, the TCP flows slow down and ramp up at different times. Since they are unsynchronized, their aggregate rate is smoother than before. From a queue-theory viewpoint, smooth traffic achieves the best utilization and shortest queue.

RED keeps track of the average queue length, calculated as an exponentially weighted moving average of the

Figure 6: RED probabilities of discarding

instantaneous queue length. The average queue length is compared to a minimum threshold, $T_{\min}$, and a maximum threshold, $T_{\max}$. The packet-drop probability is calculated with the help of an intermediate drop probability q shown in Figure 6. Below $T_{\min}$, no packets are dropped because the short queue means no congestion. Above $T_{\max}$, all packets are discarded because the long queue is a sign of serious congestion. Between $T_{\min}$ and $T_{\max}$, the intermediate drop probability q increases linearly to a maximum probability P . The actual drop probability p_{drop} is calculated as:

$$p_{\text{drop}} = \frac{q}{1 - q \cdot \text{count}}$$

where *count* is the number of undropped packets since the last dropped packet. In this way, RED attempts to drop packets in proportion to the rates of connections.

Since its introduction, RED has found wide commercial acceptance. Under certain traffic conditions, RED performs effectively if its parameters are properly tuned. However, it can be difficult to determine the proper parameters. Moreover, several problems can arise, depending on the traffic, such as unfairness, lowered throughput, and increased delay. Consequently, numerous variations have been proposed, including flow RED (FRED), weighted RED (WRED), stabilized RED (SRED) (Ott, Lakshman, and Wong 1999), BLUE (Feng et al. 2002), PURPLE

(Pletka, Waldvogel, and Manna 2003), adaptive virtual queue (AVQ) (Kunniyur and Srikant 2004), and predictive AQM (PAQM) (Gao, He, and Hou 2002), just to name a few. RED continues to be an active subject of research (Zhu et al. 2002; Bohacek et al. 2004).

CONGESTION CONTROL

Congestion control is a very broad term that is sometimes used interchangeably with *traffic control*. Here, *congestion control* refers to actions taken by hosts to prevent serious congestion. Congestion control can be classified as reactive or predictive (proactive). Reactive congestion control ameliorates congestion after it occurs. Generally, hosts observe the symptoms of congestion (packet loss and long packet delays) and then slow down. Predictive congestion control attempts to avoid congestion altogether by slowing down before the onset of congestion. Avoidance of congestion is obviously preferable, but predictive congestion control usually depends on explicit congestion information provided from the network.

Reactive Congestion Control

Reactive congestion control takes action when congestion is detected. A prime example of this approach is the congestion-avoidance algorithm in TCP. TCP takes responsibility for congestion control in the Internet because IP is too simple by design to handle congestion control. Strictly speaking, TCP does not actually avoid congestion. TCP pushes the network gently to the brink of congestion and then backs off. This is necessary because a TCP source does not know the appropriate transmission rate, and must search for it.

A TCP source limits itself by means of a congestion window. The congestion window is adjusted dynamically to the level of network congestion by an AIMD (additive increase, multiplicative decrease) algorithm (Jacobson 1988). The onset of congestion is detected by a retransmission time-out. As shown in Figure 7, a parameter *ssthresh* (slow start threshold) is set to half of the congestion window when congestion was encountered. The congestion window is closed to one TCP segment, and

Figure 7: TCP congestion-control algorithm

the congestion control algorithm goes into slow-start. In the slow-start phase, the congestion window can increase at an exponential rate as long as acknowledgments for packets are returned promptly. When the congestion window size reaches *ssthresh*, the congestion-control algorithm enters the congestion-avoidance algorithm. In this phase, the congestion window (*cwnd*) increases by one segment for every round-trip time until congestion is encountered again. The idea is that linear increase during congestion avoidance is a cautious approach to the previous congestion point. When congestion is encountered, the *ssthresh* parameter is set to half of the congestion window, and the congestion-control algorithm repeats.

Predictive Congestion Avoidance

The congestion-avoidance algorithm in TCP is forced to probe for the appropriate transmission rate by pushing the network to the brink of congestion because the IP network is incapable of providing congestion information. A capability for explicit congestion notification is preferable as a method of “early warning.” Protocols such as ATM and frame relay include explicit forward congestion indication (EFCI) and backward/forward explicit congestion notification (BECN/FECN), respectively.

Explicit congestion notification allows routers and switches to give early warning to sources before congestion occurs. This advance warning can give sufficient time for traffic sources to reduce their rates in time to avoid congestion. This is a proactive approach to avoiding congestion instead of a reactive approach to ameliorate congestion. It has been shown that explicit congestion notification improves the performance of TCP with active queue management (Yan, Gao and Ozbay, 2005).

Explicit congestion notification in the forward direction refers to marking packets as they pass through a router or switch. Packets in the forward direction are delivered to the destination, and the destination must have a separate means of communicating congestion information to the source. The overall delay is one round-trip time. For efficiency, explicit congestion notification in the backward direction goes directly to the source. However, it is harder to implement because a router or switch must find and mark a packet going in the backward direction.

The current version of IP does not include a capability for explicit congestion notification but an IETF proposal calls for using the last two bits from the TOS field in the IP packet header (Ramakrishnan and Floyd 1999). One bit for explicit congestion notification (ECN) capable transport (ECT) would allow hosts to signal whether they are capable of making use of ECN. The second bit for congestion experienced (CE) would allow routers or switches to signal a state of congestion to hosts. An open research issue is how routers should choose packets to mark (Leung and Muppala 2001).

QOS MONITORING

Observability is a prerequisite for controllability. Measurements of QoS can verify the effectiveness of traffic management and provide evidence to validate SLAs. In addition, QoS monitoring can identify network performance

problems and help to tune traffic controls (Jiang, Tham, and Ko 2000).

Network-Layer Performance Monitoring

Since the Internet has not historically supported QoS, there has not been a compelling need for sophisticated performance monitoring at the IP layer. By far, most methods and tools at the IP layer are based on *ping* (ICMP [Internet Control Message Protocol] echo and echo response messages) or *traceroute* (which exploits the time-to-live field in the IP packet header).

A few large-scale performance-monitoring projects use *ping* and *traceroute* to make regular measurements between multiple selected points in the Internet (Chen and Hu 2002). The basic idea is that performance measured on these selected routes will reflect the overall performance of the entire Internet if the monitoring points are numerous and geographically distributed. Repeated pings are an easy way to obtain a sample distribution function of round-trip time and an estimate of the packet-loss ratio (reflected by the fraction of unreturned pings). Although round-trip times measured by *ping* are important, especially for adaptive protocols such as TCP, *ping* is unable to measure one-way packet delays without additional means for clock synchronization among hosts such as a global positioning system (GPS). Another drawback to *ping* is the low priority or blocking given to pings by some networks, because pings are invasive and possibly involved in some types of security attacks.

Transport/Application-Layer Performance Monitoring

Another monitoring method is TCP bulk transfer between selected sites. One site acts as the source and another as the sink for TCP bulk transfer. The packets are recorded by *tcpdump* and analyzed for packet delay and loss.

Measurements at the transport layer are appealing because they are closer to the application's perspective. Moreover, they do not depend on ICMP or *traceroute*, which are not entirely reliable. At the transport layer, the idea is to run a program emulating a TCP session to send test traffic through the Internet. The performance of the TCP connection can be measured in terms of delay, loss, and throughput.

For example, *TReno* (*traceroute Reno*) is an emulation of TCP to measure throughput or bulk transfer capability. It combines *traceroute* and an idealized version of the flow-control algorithm in Reno TCP. Other examples are *ttcp* (throughput TCP) and *netperf*. *Ttcp* is a client/server benchmarking program to measure throughput and re-transmissions. *Netperf* is a network performance benchmarking program for measuring bulk data transfer and request/response performance using TCP or UDP (user datagram protocol). One host runs *netperf* and another runs *netserver*. Tests can be a TCP stream performance test, UDP bulk transfer, or TCP request/response test.

Similarly, network performance can be measured at the application layer. For example, NetIQ's commercial *Chariot* or Qcheck software agents are installed and configured

at hosts with scripts to emulate various applications and collect application-level performance (throughput, delay) measurements. Application-layer measurements have the advantage of measuring performance that is reflective of what applications are seeing. On the other hand, special software is needed at selected sites and it is an active monitoring method that adds traffic into the network.

CONCLUSION

As seen in this chapter, traffic management is a challenging problem covering an impressive breadth and depth. The breadth is due to various traffic controls that should work together. Moreover, many details are involved in engineering each control to work effectively.

Traffic management continues to be an active area of study, not because solutions are not possible but because many solutions are possible. The “optimal” solution continues to be elusive because many factors (fairness, effectiveness, efficiency, practicality) usually need to be considered, allowing for different opinions of optimality.

Even as next-generation networks provide more bandwidth, traffic management will still be an important problem. Next-generation networks will support a greater variety of applications. Different applications require different treatment by the network. The intelligence to recognize different traffic and their requirements implies the need for sophisticated traffic management.

GLOSSARY

Access Policing: Regulation of ingress traffic at the user-network interface.

Active Queue Management (AQM): Intelligent buffer management strategies enabling traffic sources to respond to congestion before buffers overflow.

Admission Control: An open loop control method to accept or block traffic flows before flows start.

Differentiated Services (Diffserv): An IETF framework supporting QoS classes by means of Diffserv code point marking, per-hop behaviors, and stateless core routers.

Explicit Congestion Notification: A proactive congestion-avoidance method involving routers or switches conveying congestion information to hosts.

Integrated Services (Intserv): An IETF framework supporting QoS based on RSVP reservations per flow.

Leaky Bucket: An algorithm for policing a specific traffic rate while allowing a limited variation around that rate.

Quality of Service (QoS): The end-to-end network performance defined from the perspective of a specific user's connection.

Random Early Detection (RED): An active queue management approach for preventing synchronization of TCP connections.

Resource Reservation Protocol (RSVP): An IETF standardized signaling protocol for IP networks.

Service-Level Agreement (SLA): A contract between users and a network provider or between two network

providers specifying expectations about the level of service in a way that allows monitoring and verification.

Signaling Protocol: Rules for exchanging messages to request reservations of network resources.

Traffic Contract: An implicit agreement between users and the network to meet QoS requirements as long as ingress traffic conforms to specified traffic descriptors.

Traffic Shaping: Smoothing the traffic rate to improve network performance.

INTRODUCTION

According to Williams, Pandelios, and Behrens (1999), "All projects have some level of risk associated with them." And as Carr et al. (1993) state, risks must be managed, and risk management must be part of any mature organization's overall management practices and management structure. They identify these primary activities for managing risk:

Identify: Risks must first be identified before they can be managed.

Analyze: Risks must be analyzed so that management can make prudent decisions about them.

Plan: For information about a risk to be turned into action, a detailed plan, outlining both present and potential future actions, must be created. These actions may mitigate the risk, avoid the risk, or even accept the risk.

Track: Risks, whether they have been acted on or not, must be tracked, so that management can continue to exercise diligence.

Control: Even if a risk has been identified and addressed, it must be continually controlled to monitor for any deviations.

The key activity tying all of these activities together is *assessment*. Assessment is considered central to the risk management process, underlying all of the other activities.

For the purposes of exposition, we follow Boehm's (1991) generic risk taxonomy, given in Figure 1. In this taxonomy, the activity of risk management has two major subactivities: risk assessment and risk control. Risk assessment is further divided into risk identification, risk

analysis, and risk prioritization. Risk control is divided into risk-management planning, risk resolution, and risk monitoring. Although we broadly discuss several areas of risk management, our focus in this chapter is on risk assessment, as it applies to networking and, in particular, security issues in networking. Assessment is the starting point and forms the fundamental basis for all risk-management activities. Many risk-assessment methods and techniques have directly analogous application to risk control. In such cases we note this application without elaboration.

The terminology used in the field of risk management varies somewhat among the different business and engineering areas in which it is used; for example, see Boehm (1991), Carr (1993), and Hall (1998). It even varies among writers in the field of risk management. Although most people are unaware that they are doing it, we all engage in risk management on a daily basis. Consider, as an example, a decision, made on the way out the door, whether or not to stuff an umbrella into an uncomfortably heavy bag that will be taken on a 30-minute train ride, followed by a 10-minute walk¹ to the office. The decision is based on a quick, often almost unconscious assessment of the risks involved and how to control them.

On the one hand, there is the probability that the rain predicted by the TV forecaster will actually materialize, that it will be in progress during the drive to the train station and/or during the walk, and, if all goes as badly as it might, that it will cause damage, from the point of view

¹ This example, as well as a number of others in this section, is taken, albeit with considerably more detail, from National Institute of Standards and Technology (2002).

Figure 1: Boehm's risk-management taxonomy

of both walking in drenched clothing and possibly losing work time during the drying-out period. Balanced against all these risks, on the other hand, is the discomfort of carrying the extra weight, of the possibility of having the precariously situated umbrella drop out of the bag and, as it did last week, causing a spillage of hot coffee during the effort to pick it up. An additional consideration is the probability that carrying the umbrella will solve the problem, a consideration that depends on the expected strength of prevailing winds; if the wind proves to be too strong, the umbrella will provide no relief from the rain. An alternative possibility to consider, assuming it is an option, is to work at home all morning and to go to the office only after the rain or its unmaterialized threat has abated.

Network Security Risk Assessment

Networks run the modern business world. As such, networks must provide a high degree of security if those businesses are to survive and prosper. But networks are confronted with many security risks. The following are examples of the consequences that can result from the materialization of network security risks in the specific areas of confidentiality, integrity, and availability:

- Loss of confidentiality:
 - Personal embarrassment resulting from theft and publication of personal financial, health, or other

data and possible prosecution and fines for individuals and the organization responsible for maintaining confidentiality

- Corporate loss of earnings resulting from theft of pre-patent technical data
- Loss of life of a covert intelligence agent resulting from theft and revelation of name and address
- Loss of integrity:
 - Personal embarrassment and possibly fines and imprisonment resulting from insertion into a database of false financial data, implicating the subject in fraud or embezzlement
 - Loss of corporate auditors' ability to detect embezzlement and the attendant loss of funds, resulting from deliberate corruption of financial data by an embezzler
 - Loss of life resulting from changes to a database indicating that a subject is a covert agent when he or she is not
- Loss of availability:
 - Personal embarrassment caused by an inability to keep appointments resulting from temporary inability to use electronic calendar
 - Temporary inability of corporation to issue weekly paychecks to employees, with attendant anger and loss of productivity, resulting from temporary unavailability of hours-worked data

- Loss of initiative, armaments, and lives resulting from battlefield commander's inability to connect to field-support database

The terms *threat*, *threat source*, *vulnerability*, *impact*, and *risk exposure* are in common use in the field of information security assessment. Their application to the trip-to-work scenario is as follows:

- The *threat*, or *threat source*, is the onset of rain, at a sufficiently strong level, during an exposed part of the trip to work.
- The *vulnerability* is the fact that the person involved will get drenched if the threat materializes and the person has no form of shelter (e.g., an umbrella).
- The *impact* is the damage, measured in terms of discomfort and possibly of loss of productivity or even health, that will occur if the threat materializes.
- The *risk exposure* is an assessment, on either a numerical, perhaps monetary, scale or an ordinal scale (e.g., low, medium, or high), of the expected magnitude of the loss given the threat, the vulnerability to it, and its impact, should the threat materialize. In this example, the risk exposure might change if the person is wearing a water-resistant coat.

The first step in risk assessment is *risk identification*—the identification of potential threats, vulnerabilities to those threats, and impacts that would result should they materialize—all of which we presented for the scenario under discussion.

In the trip-to-work scenario, we are concerned with such intangibles as the threat of rain, the vulnerability to getting drenched, and the impact of discomfort, as well as with tangibles such as umbrellas. In the field of networking, we are concerned with systems that store, process, and transmit data/information. Information systems are sometimes localized and sometimes widely distributed; they involve computer hardware and software, as well as other physical and human assets. Tangibles include the various sorts of equipment and media and the sites in which they and staff are housed. Intangibles include notions such as organizational reputation, opportunity or loss of same, productivity or loss of same, etc.

Threat sources are of at least three varieties: natural, human, and environmental:

1. *Natural*: electrical storms, monsoons, hurricanes, tornadoes, floods, avalanches, volcanic eruptions
2. *Human*: incorrect data entry (unintentional), forgetting to lock door (unintentional), failure to unlock door to enable confederate to enter after hours (intentional), denial of service attack (intentional), creation and propagation of viruses (intentional)
3. *Environmental*: failure of roof or wall caused by the use of bad construction materials, seepage of toxic chemicals through ceiling, power outage

Vulnerabilities have various sources, including technical failings such as those reported in the public and

professional presses on a daily basis.² Fred Cohen (Fred Cohen & Associates 2004) provides an excellent extensive taxonomy of threats and vulnerabilities in his Security Database. One unique aspect of this database is that threats (or causes) are cross-referenced against attack mechanisms to provide a linkage between the cause and the mechanisms used. The attack mechanisms are also cross-referenced against defense mechanisms to indicate which such mechanisms might be effective in some circumstances.

The second step in risk assessment is risk analysis, the estimation and calculation of the risk likelihoods (i.e., probabilities), magnitudes, impacts, and dependencies. This analysis is easy in the case of monetary impacts arising from threat-vulnerability pairs for which the probability of materializing can reasonably be computed, but is considerably harder in most other cases. Special care must be taken when assigning likelihoods, as the quality of the entire risk assessment is strongly dependent on the accuracy and realism of the assigned probabilities.

The final step in risk assessment is risk prioritization; that is, prioritizing all risks with respect to the organization's relative exposures to them. It is typically necessary to use techniques that enable risk comparison, such as calculating risk exposure in terms of potential loss. In the trip-to-work scenario, risks other than the ones discussed above might include the risk associated with not buckling the seat belt during the drive to the station, the risk of an accident during the drive, the risk of missing the train, etc. A meticulous person, one who always leaves the house earlier than necessary and who is very conscious of taking safety precautions, will likely rate these new risks as having far lower exposures than the rain risk: a less meticulous person might do otherwise. In a highly simplified version of a business situation, three threats might be volcanic eruption, late delivery of raw materials, and embezzlement. An organization located in Chicago would likely assign a lower priority to volcanic eruption than would one in southwestern Washington; an organization with suppliers that have never before been late would likely assign a lower priority to late delivery than would an organization using a supplier for the first time. Because there may be threats or vulnerabilities that you may not have included in your analysis, you should draw on the experiences of others to help build a library of threats and vulnerabilities.

Network Security Risk Control

During the risk control phase of the risk-management process, we are concerned with *safeguards*, also known as *controls*. Safeguards fit into at least three categories: technical, management, and operational:

1. *Technical*: authentication (prevention), authorization (prevention), access control (prevention), intrusion detection (detection), audit (detection), automatic backup (recovery), etc.

² A compilation of technical threats may be found at <http://icat.nist.gov> or www.cert.org.

2. *Management*: assign guards to critical venues (prevention) and institute user account initiation and termination procedures (prevention), need-to-know data access policy (prevention), periodic risk reassessment policy (prevention), and organizationwide security training (prevention and detection), etc.
3. *Operational*: secure network hardware from access to any but authorized network administrators and/or service personnel (prevention); bolt desktop PCs to desks (prevention); screen outsiders before permitting entry (prevention); set up and monitor motion alarms, sensors, and closed-circuit TV (detection of physical threat); set up and monitor smoke detectors, gas detectors, fire alarms (detection of environmental threats)

In the trip-to-work scenario, the safeguard that we have considered has a (fairly low-tech) technical component (i.e., the umbrella) and an operational component (i.e., carrying the umbrella). An alternative operational safeguard would be to work at home all morning, if that is an option, and to go to the office only after the rain or the threat of rain has abated.

During the risk-control phase of the risk-management process, we do the following:

- consider alternative individual safeguards and/or complexes of safeguards that might be used to eliminate/reduce/mitigate exposures to the various identified, analyzed, and prioritized threats (risk-management planning)
- perform the cost-benefit analysis required to decide which specific safeguards to use, and institute the relevant safeguards (risk resolution)
- institute a process for continuous monitoring of the network risk situation to detect and resolve problems as they arise and to decide, where and when necessary, to update or change the system of safeguards (risk monitoring)

In business and government organizations, there may be many possible alternative safeguards, including different vendors' hardware and/or software solutions to a particular threat or cluster of threats, alternative management or procedural safeguards, and alternative combinations of technical, management, and procedural safeguards. Complicating matters is the likelihood that different combinations of safeguards address different, overlapping clusters of threats.

Risk resolution begins with the cost-benefit analysis of the various possible safeguards and controls in lowering, to an acceptable level, the assessed risk exposures resulting from the various identified threats, vulnerabilities, and the attendant impacts. Just as we had to consider threats, vulnerabilities, and impacts during risk assessment, we must consider safeguards, their costs, and their efficacies during risk resolution. In the trip-to-work scenario, the marginal cost of the technical component of the umbrella-carrying safeguard is likely nil, as most people already own umbrellas; the operational cost is the discomfort of carrying a heavier bag. Even in this simple

example, the safeguard's efficacy must be considered. For example, if the wind proves to be too strong, the umbrella will not reduce the exposure effectively.

Risk Management in Practice

The potential consequences of the materialization of a significant threat to a business or government organization and the obvious fact that risk management can greatly reduce those consequences make it eminently clear that organizations cannot afford *not* to engage in a serious risk-management effort. The smaller the organization and the simpler the threats, the less formal the organization's risk-management effort need be. For the small organization, such as a single retail store belonging to a family, very informal risk management may suffice. In many situations, legal statutes and acquisition policies give an organization no choice. The Hawthorne Principle states that productivity increases as a result of simply paying attention to workers' environments. It is likely, by analogy, that a simple concern with risk management produces significant, though certainly not optimal, results.

However, clearly risk management is rarely easy. In the case of the rare threat-vulnerability pair for which the probability can easily be assigned a numerical value, the impact can be assigned a precise monetary value, and there exists a safeguard with a cost and efficacy that can be pinned down numerically, there is no problem. In other cases, those in which one or more of the parameters can at best be placed on an ordinal scale, matters are more complicated, and approximate methods must be used. Consider, as examples the quantification of the impact of the following:

- personal embarrassment resulting from theft and publication of personal financial, health, or other data; insertion into database of false financial data implicating the subject in fraud or embezzlement; inability to keep appointments resulting from temporary inability to use electronic calendar
- corporate loss of earnings resulting from theft of prepatent technical data
- loss of corporate auditors' ability to detect embezzlement and attendant loss of funds, resulting from deliberate corruption of financial data by an embezzler
- temporary inability of a corporation to issue weekly paychecks to employees, with attendant anger and loss of productivity, resulting from temporary unavailability of hours-worked data
- loss of life of covert intelligence agent resulting from theft and revelation of name and address caused by changes to the database indicating that subject is a covert agent when he or she is not or by the battlefield commander's inability to connect to the field-support database

To aid in the identification and management of risks, a number of risk-management methods and risk taxonomies have been created. The Software Engineering Institute's (SEI) risk taxonomy, for example, divides risk into three classes: product engineering, development environment,

Table 1: Taxonomy of Software Development Risks (from Carr et al., 1993)

Product Engineering	Development Environment	Program Constraints
1. Requirements a. Stability b. Completeness c. Clarity d. Validity e. Feasibility f. Precedent g. Scale	1. Development process a. Formality b. Suitability c. Process control d. Familiarity e. Product Control	1. Resources a. Schedule b. Staff c. Budget d. Facilities
2. Design a. Functionality b. Difficulty c. Interfaces d. Performance e. Testability f. Hardware constraints g. Non-developmental software	2. Development system a. Capacity b. Suitability c. Usability d. Familiarity e. Reliability f. System support g. Deliverability	2. Contract a. Type of contract b. Restrictions c. Dependencies
3. Code and unit test a. Feasibility b. Testing c. Coding/implementation	3. Management process a. Planning b. Project organization c. Management experience d. Program interfaces	3. Program interfaces a. Customer b. Associate contractors c. Subcontractors d. Prime contractor e. Corporate management f. Vendors g. Politics
4. Integration and test a. Environment b. Product c. System	4. Management methods a. Monitoring b. Personnel management c. Quality assurance d. Configuration management	
5. Engineering Specialties a. Maintainability b. Reliability c. Safety d. Security e. Human Factors f. Specifications	5. Work environment a. Quality Attitude b. Cooperation c. Communication d. Morale	

and program constraints. The first level of decomposition of each of these classes is given in Table 1.

This taxonomy is used to “drive” a risk-assessment method. For each class (such as product engineering), and for each element within that class (such as design) and for each attribute of that element (such as performance), there are a set of questions that guide the risk analyst. Depending on the answers to these questions, the analyst might be guided to still further questions that probe the nature of the risk. For example, an analyst looking at performance risks would first ask whether a performance analysis has been done. If the answer is “yes,” a follow-up question would ask about the level of confidence in this analysis. Note that security is just one attribute, located under the engineering specialties element. Clearly, to be able to manage security risks we need to delve more deeply into the elements and attributes that are particular to security. We give some examples of risk-management methods tailored for security in the next section.

NETWORK SECURITY RISK-ASSESSMENT METHODS

Risk management is the process of identifying, controlling, and minimizing or eliminating risks that may affect information systems, for an acceptable cost. This chapter has thus far addressed risk assessment. Now we turn to the broader topic of integrating risk assessment with risk management. The notion of risk management was briefly introduced in the previous section. In this section we examine and compare some of the most common and widely used assessment methods for network security risk management: the Operationally Critical Threat, Asset, and Vulnerability Evaluation (OCTAVE 2004) method, and the Survivable Network Analysis Method (Mead et al., 2000), both developed by the Computer Emergency Response Team (CERT) at Carnegie Mellon University (Alberts and Dorofee 2002); and the Facilitated Risk Assessment Process (FRAP), developed by Peltier and colleagues (2003).

There are other forms of risk assessment that may be applied to understanding risks in networks, such as fault tree analysis, probabilistic risk assessment, event trees, and so forth, but we will restrict our attention in this chapter to looking at network *security* risk, since that is the largest source of risk exposure for most organizations.

To facilitate comparison of these risk-assessment methods, we look at their steps and their organization, examining how they do the following:

- establish *context and goals* for the analysis
- *focus* the inquiry
- perform the *analysis*
- *close the loop*, tying analysis outcomes back to their original goals

By examining each of the analysis methods in terms of these categories, we can see where each method places its emphasis.

OCTAVE

The OCTAVE (2004) approach describes a family of security risk evaluation methods that, unlike many other security analysis methods, are aimed at finding *organizational* risk factors and strategic risk issues by examining an organization's security practices (Alberts and Dorofee 2002). Its focus is not on finding specific risks within specific systems, but rather to enable an organization to consider all dimensions of security risk so that it can determine strategic best practices. The OCTAVE approach thus needs to consider not only an organization's assets, threats, and vulnerabilities, as any security method would, but it also asks the stakeholders to explicitly consider and evaluate the organizational impact of security policies and practices. For this reason, an organization's evaluation team must be multidisciplinary, comprising both technical personnel and management.

The OCTAVE process is organized into three phases that are carried out in a series of workshops. In Phase 1—Build Asset-Based Threat Profiles—the team first determines the context and goals for the analysis by describing

the information-related assets that it wants to protect. The team does this via a set of structured interviews with senior management, operational management, information technology (IT) staff, and general staff. The team then catalogs the current practices for protecting these assets. The OCTAVE approach then focuses the inquiry by selecting the most important of these assets as *critical assets*, which are the subject of the remainder of the analysis. The evaluation team identifies a set of threats for each critical asset.

In Phase 2—Identify Infrastructure Vulnerabilities—the analysis team performs the analysis by first identifying a set of components that are related to the critical assets and then determining the resistance (or vulnerability) of each component to being compromised. They do this analysis by running tools that probe the identified components for known vulnerabilities.

Finally, in Phase 3—Develop Security Strategy and Plans—the team closes the loop. It examines the impact of the threats associated with each of the critical assets based on the Phase 2 analysis, using a common evaluation basis (for example, a determination of high, medium, or low impact). Based on these evaluations the team determines a course of action for each: a risk-mitigation plan. Instead of merely determining a tactical response to these risks, the goal of the OCTAVE analysis is to determine an organizational “protection strategy” for the critical assets.

As an approach that is aimed at strategic organization-wide risk reduction, OCTAVE also includes activities to ensure that the organization monitors and improves its processes. These risk reduction activities revolve around planning in detail how to implement the protection strategy, implementing the plans, monitoring the plans as they are being implemented to ensure that they are on schedule and are effective, and finally correcting any problems encountered. Thus, the three phases of the OCTAVE approach can be seen as part of a larger picture, encompassing the activities shown in Figure 2.

The OCTAVE approach has been instantiated in two methods to date: OCTAVE and OCTAVE-S. OCTAVE is aimed at large organizations with large, complex information security requirements and infrastructures. OCTAVE-S, on the other hand, is aimed more at smaller

Figure 2: OCTAVE phases

organizations (or smaller subunits of large organizations) with simpler information security needs.

SNAM/SSAM

The SNAM (Survivable Network Analysis Method) (Mead et al. 2000), and its successor the SSAM (Survivable Systems Analysis Method) were created to systematically assess the survivability properties of complex systems. The method consists of a series of working sessions, in which analysts meet with system stakeholders, and results in a briefing on findings and recommendations.

The SNAM method is composed of four steps, as follows:

- **Step 1, System Definition:** To start, the business goals and mission objectives of the system, current set of requirements, details on the system architecture, and known risks from the operational environment are elicited from the system stakeholders. The capabilities and locations of system users, and the types and volumes of system transactions are recorded. Known system risks are reviewed.
- **Step 2, Essential Capability Definition:** Next, essential services and assets (assets whose integrity, confidentiality, availability, and other properties must be maintained during attack) are identified. These essential services and assets are characterized as *scenarios*. The scenarios are traced through the architecture to identify essential components whose survivability must be ensured.
- **Step 3, Compromisable Capability Definition:** A set of representative intrusion scenarios are selected based on assessment of the environment: both known risks and intruder capabilities. These scenarios are mapped onto the system architecture and their execution is traced through the system's representation as a means of identifying components that might be compromised (damaged by some intrusion).
- **Step 4, Survivability Analysis:** Finally, "soft spot" components of the architecture—components that are both essential and compromisable (based on the outputs of steps 2 and 3)—are now analyzed. These components are examined in terms of their "survivability" properties: resistance, recognition, and recovery. The analysis of these "three Rs" is summarized in a Survivability Map. The map enumerates, for every intrusion scenario and corresponding soft-spot effects, the current and recommended architecture strategies for resistance, recognition, and recovery. The Survivability Map provides feedback to the original architecture and system requirements, and gives management a roadmap for survivability evaluation and improvement.

The SNAM produces the following deliverable items for the system being analyzed:

- A list of system business and mission goals and key requirements
- An inventory of essential services and assets, and essential system architecture components

- A set of scenarios describing potential intrusions
- An identified set of compromisable system architecture components
- A list of architecture vulnerabilities and soft spots
- A determination of mitigation strategies for resistance, recognition, and recovery of each soft spot
- A system survivability map

These deliverables are provided in a final report and briefing, and provide a basis for risk analysis, cost-benefit trade-offs, and system improvement.

The Survivable Network Analysis method has helped organizations be proactive in defining, designing, and implementing system improvements to deal with inevitable intrusions and compromises. The SNAM process raises awareness of survivability exposures in systems; it helps avoid "unpleasant surprises" by providing a management roadmap for addressing exposures before the fact.

FRAP

The Facilitated Risk Assessment Program (FRAP) is a qualitative process developed by Thomas Peltier and colleagues (Peltier et al. 2003). In the FRAP, a system or a segment of a business process is examined by a team that includes both business/managerial and IT personnel. The FRAP guides them to brainstorm potential threats, vulnerabilities, and the potential damages to data integrity, confidentiality, and availability. Based on this brainstorming, the impacts to business operations are analyzed, and threats and risks are prioritized. The FRAP is purely qualitative, meaning that it makes no attempt to quantify risk probabilities and magnitudes. It has three phases, as discussed below.

Phase 1: The Pre-FRAP Meeting

In Phase 1, the initial team members are chosen, and the team determines the scope and mechanics of the review. This process establishes the context and goals of the inquiry. The outputs of Phase 1 are a scope statement, an identification of the team members (typically between 7 and 15 people), a visual model of the security process being reviewed, and a set of definitions. These definitions serve as an anchor to the rest of the process. The FRAP recommends that the team agrees on the following terms: *integrity*, *confidentiality*, *availability*, *risk*, *control*, *impact*, and *vulnerability*. Finally, the mechanics of the meeting need to be agreed on: location, schedule, materials, etc.

Phase 2: The FRAP Session

Phase 2 is divided into three parts. These three parts serve as the focusing activity, as well as the front end of the analysis activity. The first activity is to establish the logistics for the meeting: who will take what role (owner, team leader, scribe, facilitator, team member). Once this is done, the team reviews the outputs from Phase 1—the definitions, scope statement, and so forth—to ensure that all team members start from a common basis of understanding. The second activity is brainstorming, in which all of the team members contribute risks that are of concern to them. The third and final activity is prioritization.

Prioritization is ranked along two dimensions: vulnerability (low to high) and impact (low to high). When the risks are documented, the team also contributes suggested controls for at least the high-priority risks.

Phase 3: The Post-FRAP Meeting(s)

Phase 3 may be a single meeting or may be a series of meetings over many days. In this phase the bulk of the analysis work is done, as well as closing the loop. The outputs from the phase are a cross-reference sheet, an identification of existing controls, a set of recommendations on open risks and their identified controls, and a final report. Producing the cross-reference sheet is the most time-consuming activity. This sheet shows all the risks affected by each control, as well as any trade-offs between controls that have been identified. In addition to documenting everything that has been learned in the FRAP, the final report contains an action plan, describing the controls to implement.

Quantitative versus Qualitative Approaches

The security risk management methods described above differ in whether they attempt to quantify security risks or to assess and prioritize risks qualitatively. The OCTAVE process approaches the problem of identifying, analyzing, planning for, and managing security risks quantitatively (in the OCTAVE approach, quantitative analysis of risks is an optional element of phase 3). The FRAP, SNAM, and OCTAVE-S, on the other hand, are purely qualitative. What are the costs and benefits of each approach?

Neither approach is obviously superior to the other. Quantitative methods tend to be more expensive and time consuming to apply and require more front-end work, but they can produce more precise results. Such methods tend to be associated with higher-process mature organizations. Qualitative methods, on the other hand, are less time consuming (and therefore more agile to apply) and require less documentation. In addition, specific loss estimates are often not needed to make a determination to embark on a risk mitigation activity.

In the section on “Practical Strategic Risk Models,” we will show how a quantitative security risk assessment practice can be implemented that is not unduly time or resource consuming.

RISK MODELS

At the start of this chapter the fundamental vocabulary and techniques of risk assessment and risk management were introduced. Now we discuss how risk assessment applies to risk management decision making. Our focus will be on “strategic” methods—methods that plan from the outset to achieve particular goals regardless of the circumstances rather than “tactical” methods, which attempt to make the best response in a given circumstance. To do this, we need to take some of the terms that we defined informally above and give them more precise definitions.

Definitions

A *risk*, from the network security perspective, is the potential of loss or damage from some threat that

successfully exploits a vulnerability of the network. Risk generally has two dimensions—likelihood and size. The higher the likelihood that a threat will succeed, and the greater the size of the potential loss, the greater the risk to the network.

A *threat*, then, is a stimulus for a risk; it is *any* danger to the system; an undesirable event. A threat, however, might not be a person. The threat itself is not a risk, rather only the possible consequences of that threat incurs risk (i.e., empty threats have no risk). A “threat agent” is a person who initiates or instigates a threat. Typically a threat will take advantage of some network *vulnerability*—a condition in which the system is missing or improperly applying a safeguard or control. The vulnerability increases the likelihood of the threat or its impact, or possibly both. It is important to note that the “network” includes people, not just hardware and software.

The net effect of a vulnerability being exploited by a threat agent is to expose the organization’s network-accessible assets to a potential loss. This loss might be in the form of a loss or disclosure of private information, a corruption of the organization’s information (a loss of *integrity*), or a denial of services.

In the language of risk, we need to consider simultaneously the magnitude (size) and probability (likelihood) of a risk. A simple quantification of risk in terms of risk exposure (RE) (Boehm 1991) is:

$$RE = \text{probability(loss)} * \text{magnitude(loss)}$$

This is frequently written as $RE = P(L) * S(L)$. For example, if organization A calculates the probability of a key server being down for 2 hours as 10% due to denial of service attacks, and the resulting loss due to the down time to be \$20,000, then the risk exposure facing A due to this loss is \$2,000

Under general circumstances, we will see that the total potential loss due to a combination of risks is simply the sum of the individual RE. This leads to the *basic risk formula*, which frequently is presented as a summation of all sources of loss to which a network is exposed, therefore:

$$\text{Total RE} = \sum P(L_i) * S(L_i)$$

where L_i is the loss due to the i th risk. For example, if organization A has two other risks that they are facing, one with a probability of 50% and a loss of \$1,000 and another with a probability of 0.1% and a loss of \$1,000,000 then A’s Total RE is:

$$\begin{aligned} &.1 * \$20,000 + .5 * \$1,000 + 0.001 * \$1,000,000 \\ &= \$2,000 + \$500 + \$1,000 \\ &= \$3,500 \end{aligned}$$

Related to the notion of RE is *risk reduction leverage* (RRL). RRL is a way of gauging the effectiveness or desirability of a risk reduction technique. The formula for RRL is:

$$RRL = (RE_{\text{before}} - RE_{\text{after}}) / RRCost,$$

where $RRCost$ stands for risk reduction cost. A similar formula can be used to compare the relative effectiveness of technique A with respect to B:

$$RRRL_{A,B} = (RE_B - RE_A) / (RRCost_A - RRCost_B),$$

where RE_A and RE_B are the risk exposures after using A and B, respectively (we assume that the RE before applying the techniques is the same for both techniques). We see that when $RRRL_{A,B} > 0$, technique A is more cost-effective than technique B.

Let us consider an example. Say an organization is considering ways of lowering its risk on a safety-critical network (such as an emergency communications network), and has identified a structured walkthrough or an IV&V (independent validation and verification) activity as two possible ways of finding vulnerabilities and hence reducing the risk. It may proceed as follows; first, it must establish a cost for each risk-reduction technique. Next, it must evaluate its current RE (which is its RE_{before}) and the RE that will result from the application of the technique (the RE_{after}). Let's assume that the organization is interested in the risk involved with the safety-critical network failing. Such a failure would result in a loss to the organization of \$10,000,000, and currently the organization believes that there is a 5% likelihood of such an occurrence. Structured walkthroughs have, in the past, been shown to find 80% of the outstanding problems, reducing the probability of a loss to 1%. IV&V is even more effective at finding problems, and it is expected that this technique will reduce the probability of a loss to 0.01%. However, the structured walkthrough is relatively inexpensive, costing just \$5,000 (the time of the employees involved). The IV&V, since it is independent, involves hiring a consultant, which will cost \$100,000. The RRL for each technique can now be calculated as follows:

$$\begin{aligned} RRL_{inspection} &= (.05 * 10,000,000 - .01 * 10,000,000) / 5,000 \\ &= (500,000 - 100,000) / 5,000 \\ &= 80 \end{aligned}$$

$$\begin{aligned} RRL_{IV\&V} &= (0.5 * 10,000,000 - .0001 * 10,000,000) / 100,000 \\ &= (500,000 - 1,000) / 100,000 \\ &= 4.99 \end{aligned}$$

Clearly, in this case the organization will want to choose to do the inspection first, as its RRL is far greater than the IV&V activity. However this could also be directly seen using:

$$\begin{aligned} RRRL_{inspection, IV\&V} &= (.0001 * 10,000,000 - .01 * 10,000,000) / (5,000 - 100,000) \\ &= (1,000 - 100,000) / (-95,000) \\ &= (-99,000) / (-95,000) = 1.042 > 0 \end{aligned}$$

Figure 3: An idealized risk-reduction profile

It is often the case that a technique reduces only the likelihood of a risk and not its magnitude. In this case, the RRL reduces to the cost-benefit (CB):

$$CB = [P_{before}(L) - P_{after}(L)] * S(L) / RRCost = \Delta P(L) * S(L) / RRCost$$

Finally, another thing we can do with RE is to develop a *risk profile* (or *RE profile*) with respect to some measure of interest. For example, one can evaluate RE as a function of a monotonically increasing quantity such as elapsed time, cumulative effort, or cumulative cost. An illustrative risk profile is given in Figure 3.

Given this basis of understanding, we are now in a position to begin looking at specific techniques for strategic risk management.

Strategic Risk Models

Every network in operation will have some degree of security risk. Recall that security risks are possible situations or events that can cause a network harm and will incur some form of loss. Security risks range in impact from trivial to fatal and in likelihood from certain to improbable. Thus far we have only discussed risks that are either “identified,” in that they arise from anticipated threats and known vulnerabilities; however, there are also *unidentified* risks, for which this is not the case. Similarly, the impact of an identified risk is either known, meaning the expected loss-potential has been assessed, or unknown, meaning the loss potential has not or cannot be assessed. Risks that are unidentified or have unknown impacts are sometimes loosely labeled as *risks due to uncertainty*. In the case of network security, risk considerations often must focus on uncertainty, since by design, identified known risks are either addressed or accepted as being within a “tolerable” level. Managing risks due to uncertainty is essentially the focus of sound *risk management*. Finally, note that a *risk model* describes risks and their impacts for a particular system.

We consider risk-profile models because risks are generally not static. Likelihoods and impacts change with a number of factors such as time, cost, network state, size,

number of users, and so forth. As a consequence it is often desirable to consider risks with respect to a planned set of events such as assessment effort, network operation time, number of nodes, development investment, etc. Representations of risks that dynamically change over planned activities are called “strategic risk models.” We would like to use these models to promote effective risk management.

As introduced above, we will use risk *profiling*. Recall that RE is computed as the product of the probability of loss and the size of that loss summed over all sources for a particular risk. Since security risk considerations greatly affect a network’s operational value, it is important that these risks be investigated candidly and completely. Expressing network development and operation considerations in terms of risk profiles enables quantitative assessment of attributes that are typically specified only qualitatively. A useful property of RE is that if it is computed entirely within a particular system (i.e., no external loss sources), we may assume that all RE sources are *additive*. This will be true regardless of any complex dependencies and is analogous to mathematical expectation calculations within classic probability theory.

The additivity of RE can be exploited to analyze strategies for managing risk profiles for network security. Such analyses enable cost, schedule, and risk trade-off considerations that help identify effective risk-management strategies. In particular, this approach can help answer difficult questions such as: What particular methods should be used to assess these vulnerabilities? Which method should be used first? and How much is enough [risk assessment, risk mitigation, or risk control]? As in previous sections, our focus will be on risk assessment, noting that the methods presented often have analogous counterparts in risk control.

Strategic Risk Management Methods

The purpose of risk modeling is to aid in risk-management decision making. Management does not necessarily mean removing risk; this is not always possible or even practical. For any risk, there is usually only a limited degree to which that risk can be avoided, controlled, or mitigated (i.e., expected loss reduced). As indicated earlier, there are risks due to uncertainty that cannot be mitigated or even assessed. As such, risk management is the collection of activities used to address the identification, assessment, mitigation, avoidance, control, and continual reduction of risks within what is actually feasible under particular conditions and constraints. As such, the goal of risk management is one of “enlightened gambling,” in which we seek an expected outcome that is positive (or as low-risk as practical), regardless of the circumstances. Assessment is the key starting point and, as stated earlier, the focus of this chapter. This includes gaining insight into the following:

- what the risks are and where there is risk due to uncertainty
- differentiating between development risks and operation risks
- avoidable versus unavoidable risks

- controllable versus uncontrollable risks
- cost and benefits of risk mitigation, avoidance, and control

Assessment enables a strategy to be chosen for the mitigation and control of risk. However, it is not obvious from the outset that any given assessment strategy will be effective (or even feasible). In fact, a poorly chosen strategy may actually *increase* overall risk. A strategic risk management method is one that produces a risk-management strategy that reduces overall risk with respect to a particular goal (e.g., most risk reduction at lowest cost). Having a particular goal here is firmly predicated on having acceptable, well-defined strategic risk models, as described above.

We will now describe models and methods for the strategic risk management of IT system security. Such models and methods will aid in making important “pre-crisis” risk-management decisions by determining how much effort (or time) should be invested assessing security risks with respect to project risk factors such as cost, schedule, launch (or operation) window, available skills and technology, uncontrollable external events, and so forth. In this way, we lay the foundation for a practical, economically feasible, empirically based approach for the strategic planning of risk-management efforts.

The Need for Strategic Risk Management Methods

To illustrate the need for strategic risk management we consider a general IT security risk assessment. The risk exposure corresponding to the cumulative potential loss from security violations in the operational network (e.g., intrusions) will be called $RE_{security}$. In the case of network security risk assessment, the more assessment that is done, the lower $RE_{security}$ is that results from unforeseen or uncontrolled vulnerabilities (i.e., uncertainty) such as those listed in Table 1. Assessed security attributes reduce both the size of loss due to “surprises” and the probability that surprises still remain. Prior to embarking on a security risk assessment, the network will likely contain many potential vulnerabilities, either known or from uncertainties. This results in an initially high (relative to the project) probability of loss— $P(L)$ —value. In this, some may be critical, and so $S(L)$, the size of the loss, will be high. Thus, without any assessment $RE_{security}$ initially will be high. When assessment has been used, the likelihood of unidentified vulnerabilities will be reduced. If assessment is done thoroughly (and identified vulnerabilities are addressed), most of the vulnerabilities remaining are likely to be minor, and $RE_{security}$ will be low.

It is generally not feasible to be totally exhaustive when performing a system assessment. As a result, the ideal assessment risk-reduction profile (as illustrated in Figure 3) is where $RE_{security}$ decreases as rapidly as possible at the beginning. This profile is ideal because it provides the maximum risk reduction for an arbitrary amount of security assessment effort. As stated previously, most strategies are nonideal, and the ideal profile must be expressly sought.

To give a concrete example of how a nonideal risk-reduction profile may occur, consider the data in Figure 4

Figure 4: Example of $RE_{security}$ profiles

taken from a space systems ground-control network. The data were generated by assessing each relevant security attribute in Table 2 for S(L), in terms of percentage of the project value lost that would result from the exploitation of a vulnerability in this attribute; and $\Delta P(L)$ for the corresponding change in probability (as a percentage) of an exploitation occurring. These, in turn, are used to calculate the corresponding RE reductions if the attribute is fully assessed. The RE has been normalized to the fractional portion of the total known RE that can be reduced through assessment. The cost is effort in hours used to perform the assessment of the attribute. Each attribute was assessed using an extensive security review checklist for that attribute.

We see that some care must be taken in choosing the order (i.e., strategy) to perform the assessments to achieve the ideal risk reduction profile illustrated in Figure 3. Figure 4 compares the RE profiles of four strategies for

performing the assessments. Each tick mark on the graph for each RE profile corresponds to the assessment of a particular attribute. Note that if the attributes are assessed in an arbitrarily order (i.e. the “arbitrary strategy”), the curve will typically look like the approximately linear curve indicated in the top of Figure 4 and clearly does not achieve the ideal of Figure 3. Another strategy is simply to do the least-cost assessments first. This generally results in the non-ideal $RE_{security}$ reduction profile indicated in the second to the top curve in Figure 4. A common recommended strategy is to prioritize the assessments from highest RE reductions first. Indeed, this will deliver a significant improvement over the other strategies discussed as indicated in the third to the top RE profile in Figure 4, however it is still not ideal. It is seen that performing the assessments in the order of highest cost-benefit (CB) will archive the desired $RE_{security}$ reduction profile. It can be shown that under fairly general circumstances, this will always be true.

We illustrated the strategic method with only risk assessment, but analogous methods exist for risk control. The important point here is that without a strategic approach, you are likely to end up with a less than ideal $RE_{security}$ reduction profile as indicated in Figure 4, resulting in inefficient use of your risk-management resources. This should not be taken lightly because frequently all assessment tasks are not, or cannot be, performed. Typically, assessment efforts are terminated when an arbitrarily defined budget is expended (rather than completed assessments), or when people “feel” as though enough risk has been reduced, or more commonly, when higher priority is given to tasks other than risk management. The outcome is a network with a high degree of risk due to uncertainty, resulting in the predictable consequences for “blind” risk taking (Basili and Boehm 2001; Tran and Liu 1997).

Practical Strategic Risk Models

In this section we look at how strategic methods may be applied in practice. This includes using strategic models to help make complex planning decisions such as “How much is enough risk assessment?” and extending the strategic method to account for multiple techniques.

Multitechnique Strategic Methods

To begin with, note that in our particular example the differences between risk-reduction strategies do not appear very pronounced. One reason for this is purely an artifact of the normalization of the RE scale. If *absolute* RE is used (that is, the actual risk is removed rather than the relative risk reduced), the difference will become more pronounced. There is a small concern that the absolute risk-reduction profile may not be consistent with the relative-risk reduction profile. However, under general circumstances it can be shown that an optimal relative risk-reduction implies an optimal absolute risk-reduction profile.

The application of a strategic method assumes that we are able to generate practical strategic risk models. From the above discussion it is clear that we always want to apply the most appropriate and effective risk-management approach for each risk. Allowing for multiple

Table 2: Examples of Network Security Attributes

A1: Denial of service	A8: File deletions
A2: System crash	A9: Access to private data
A3: Message queue overflow	A10: Hardware Failure
A4: System fault	A11: Access to code
A5: Mised operator	A12: Resource utilization
A6: Unauthorized access	A13: Requirement consistency and completeness
A7: Unauthorized administrator	A14: Understandability

assessment techniques can greatly increase the risk-reduction cost-benefit ratio. How to do this in general is not entirely without complications. For example, in generating a multiple-attribute strategy we must account for the possibility that for some attributes, a particular assessment technique may not apply (e.g., model checking for unauthorized administrator) or may not be cost-effective (e.g., prototyping for misled operator). We now present an algorithm that generates a practical, cost-effective strategy for multiple attributes and respective assessment techniques. We assume that each attribute is to be assessed only once by exactly one technique (i.e., we do not allow partial assessment with one technique then further assessment with another). Our goal here is to first choose which technique is best to use for each particular attribute, then choose in which order to perform the techniques to achieve an ideal absolute risk reduction with respect to cost, as illustrated in Figure 3. The following algorithm will generate such a strategy:

Step 1: Identify the most significant system assessment attributes. Label them $A_1, \dots, A_n$

Step 2: Identify the most significant assessment techniques (e.g., product testimonials, prototyping, etc.) applicable to the project and available resources (e.g., staff skills, tools). Label them $T_1, \dots, T_n$

Step 3: Estimate the relative probabilities $P(A_i)$ and size $S(A_i)$ quantities for potential losses associated with attributes $i = 1, \dots, n$ before any assessment. If desired $RE(A_i)$ can be estimated directly, perhaps from historical data.

Step 4: Estimate the cost $C(A_i, T_j)$, size $S(A_i, T_j)$, and probability $P(A_i, T_j)$ after assessment of A_i with T_j and the change in risk exposures $\Delta RE(A_i, T_j) = P(A_i) * S(A_i) - S(A_i, T_j) * P(A_i, T_j)$

Step 5: Calculate the benefit matrix $B(A_i, T_j) = \Delta RE(A_i, T_j) - C(A_i, T_j)$. For each A_i find the T_k where $B(A_i, T_k)$ is maximum. Set $c_i = k$.

Step 6: Calculate the RRL list, $RRL(A_i, T_{c_i}) = \Delta RE(A_i, T_{c_i}) / C(A_i, T_{c_i})$ for $i = 1, \dots, n$. Let $T(k) = (r_i, c_i)$ be the values for the corresponding attribute r_i , technique c_i of the k th largest element in the RRL list. That is, $T(1)$ is the maximum $RRL(A_i, T_{c_i})$ and $T(n)$ is the minimum.

Step 7: Graph the cumulative RE drop, $RE(n) = RE_{\text{total}} - \sum_{k=1}^n \Delta RE_{T(k)}$ versus cumulative effort $C(n) = \sum_{k=1}^n C_{T(k)}$.

The preceding process produces an ideal RE_{security} risk-reduction strategy as presented, and it easily generalizes to risk-control management activities. The strategy dictates to perform $T(k)$ for $k = 1, 2, 3, \dots$ until the cost outweighs the benefit (i.e. $RRL_{T(k)} < 1$) unless other risk reduction goals are desired (this will be discussed further in the next section). The algorithm assumes that the entire effort allocated for each $T(k)$ will be expended and then the attribute will not be assessed further. As a result, there may be more optimal strategies that allow for partial effort using multiple techniques per attribute. Multiple-attribute optimization techniques such as using simulated annealing could potentially be applied to find these but will not be discussed further here. Since the algorithm is somewhat involved, an example to illustrate it is presented in Tables 2a, 2b, 2c, 2d, and 2e, resulting in the RE_{security} reduction strategy displayed in Figure 5. For a technique that is not applicable to a given attribute, an 'X' is placed in the relevant values and these are excluded from the calculations.

Although this appears to be somewhat complex at first, the algorithm is actually fairly straightforward to implement and use. For example, the all analysis for this example could be done completely within a spreadsheet.

Strategic Decision Making and Competing Risks

With strategic risk models, the strategic method can be used to provide practical answers to difficult questions such as “how much is enough?” risk assessment, mitigation, or control activities. This question is critically important because in practice it is not feasible to implement exhaustive risk reduction due to constraints on resources (e.g., budget, personnel, schedule, technology limitations). Even without such constraints, it is frequently impossible to reduce a risk to zero or even to determine all possible risks for any given system. The best we can strive for is to reduce risk as much as possible within the given resources and uncertainties.

Recall that as we saw in our example in Figure 4, in the single technique case ordering risk-reduction activity from highest to lowest RRL results in the “ideal” risk-reduction profile. It can be shown that, with respect to cost considerations, this is the optimal ordering for reducing risk when only a fraction of the risk-reduction activities will be performed. That is, if risk-reduction activity

Table 2a: Attribute Size and Probability of Loss (Steps 1, 2, and 3)

	misop	syscr	sysft	unacc	denos	RE_{total}

Strategic Order**Figure 5:** $RE_{security}$ reduction $T(k)$ (step 7)

is stopped at any point, there is no other ordering that reduces more risk and leaves less total risk when the remaining activities are not done. The algorithm described above extends this to the use of multiple techniques. In the strategic model if cost is the only consideration, then a natural answer to how much is enough is when the cost exceeds the risk reduction benefit. Since the ordering of RRL is decreasing, there will be no activity beyond this point that would decrease the risk more than the cost for any of the previous activities.

The difficulty with using this stopping point is that it only accounts for cost with respect to the investment in security risk reduction activity. Furthermore, it assumes that cost and risk are equally exchangeable. In practice, this is not typical, and moreover, management activities always imply direct or collateral risks. For example, a system patch may do a marvelous job plugging a critical network vulnerability for a type of operating system virus, but perhaps it also takes a long time to implement and disseminate, is difficult to install, and slows the system significantly or causes it to be unstable or keep important applications from running. The resulting loss in productivity to the installed base may prove significant. A more prudent action may be to quickly release a means of identifying and removing the particular virus threat at hand and perhaps delay the deployment of a

patch. In this example, the risk-reduction activity of developing and disseminating a patch may indirectly but consequently increase the overall system risk despite the worthy, cost-effective investment in its deployment. The challenge here is of *competing dependent risks*. That is, while one activity is reducing risk, there is another (event or activity) simultaneously increasing risk, and it is unclear which could be the cause of a loss. What is clear is that the benefits of risk reduction investments are negated when an increasing risk is greater than the decreasing risk, since in such cases the overall risk increases. When a competing dependent risk is simply proportional to the cost, it can be easily accounted for in $RE_{security}$ as an additional factor in its computation. This is typically an unrealistic assumption to make given that in general, increasing security decreases access in a disproportionate way. Such decreases in access, while often important from a security perspective, may also negatively impact the usability of a network, as will be elaborated next.

Usability Risk

Our system patch example is only one indication of competing dependent risks. There are a host of others that as a group impact the ability of users to make effective use of a network. For this exposition, we refer to such considerations collectively as *risk with respect to usability* or $RE_{usability}$ and these risks are of a fundamentally different nature than $RE_{security}$. Such risks can negatively impact or even paralyze a system to the point that the system will fail to meet its intended operational goals. $RE_{usability}$ may result in losses due to nonuse of the system when required or expected, from dissatisfied customers and users, or from productivity losses when system functions are inaccessible or unreliable. $RE_{usability}$ will monotonically increase since $RE_{usability}$ represents the cumulative potential losses resulting from the inability to make effective use of a network system. We assume that a system starts out with no risk of usability and that any network security risk management effort expended contributes to the overall increase in usability risk. Calculating $RE_{usability}$ can pose a considerable challenge, as usability concerns are often relative to the characteristics of the user (e.g., patience, attention to detail, urgency in job activities, etc.). Fortunately, for our needs a crude approximation of $RE_{usability}$ will be sufficient. To address this, we note that it has been empirically suggested that because of compounding of factors, $RE_{usability}$ increases supralinearly (Platt 1999). Owing to this, a reasonably good approximation of the $RE_{usability}$ risk profile can be generated through the identification of a few well-chosen successive data points. Here we consider the following three “critical points” to be relevant:

Point 1:—Usability problems identified (or identifiable).

During the analysis and design of network security efforts, usability problems may be identified, but the full impact of these has not yet been assessed or experienced. This is early in the network security management effort (small cost investment) and increases overall usability risk moderately, as losses are not widely being realized.

Point 2:—Usability problems reported, After initial deployment of some network security measures, usability is notably impacted and losses are being realized.

Point 3:—System is effectively unusable. When overly aggressive network security measures are taken, the network may become unstable, effectively inaccessible, or too cumbersome to use (e.g., draconian access policies). The system no longer realizes its intended value by the users. When losses due to this are unrecoverable (e.g., corrupted data, shut-out users, missed business opportunities, etc.) then it is considered “effectively unusable.”

The schedule for points 1, 2, 3 are necessarily sequential, and the amounts of time (in terms of effort or cost expended) to arrive at these points are cumulative; hence $RE_{usability}$ is successively nondecreasing at these points. Moreover, the change in $RE_{usability}$ between points 1 and 2 can never be less than that between the starting point and point 1; similarly for points 2 and 3. The critical points for our example project are contained in Table 3 and the resulting $RE_{usability}$ profile is illustrated in Figure 6.

As is evident in our example, creating appropriate risk models (e.g., $RE_{security}$, $RE_{usability}$) requires an organization to accumulate a fair amount of calibrated experience on the nature of the risks, their probabilities, and their magnitudes with respect to the risk-management effort (e.g., cost, duration). In general this can be challenging and costly; however, there are many practical approaches and software tools that address these topics specifically

Table 3: Example of $RE_{usability}$ Critical Points

Point	S(L)	P(L)	RE	Cost
Identified	138400	0.15	20760	8850
Exploited	311400	0.4	124560	29500
Total loss	622800	0.9	560520	64900

Figure 6: Example $RE_{usability}$ profile

(see, for example, Tran and Liu 1997; Ochs et al. 2001; Hall 1998; Boehm 1991).

Balancing Competing Risks for Strategic Network Security Planning

The general approach in answering a “how much is enough network security” question in the face of competing dependent risks is to optimize $RE_{security}$ with respect to $RE_{usability}$. Depending on the models used, this amounts to “balancing” the risk-reduction benefit of risk management and control activities with risk increases due to cost expenditures of dollars, effort, schedule, accessibility, and so forth.

Consider again our risk assessment example. We have noted previously that it is important to have an efficient strategy for reducing $RE_{security}$ and that such a strategy may be generated by assessing the attribute-technique pairs and applying the strategic method described in the section on “Multitechnique Strategic Methods.” We have indicated that security measures reduce $RE_{security}$ by removing system vulnerabilities while simultaneously increasing $RE_{usability}$ due to their imposition on access. Too much security will put the system increasingly at risk, as it exceeds the $RE_{usability}$ critical points. However, too little security will leave the system with too much risk because of uncertainty within the vulnerabilities. The ideal security strategy decreases $RE_{security}$ but does not expend so much effort that this reduction is dominated by $RE_{usability}$. This is a formal response to the “how much is enough?” question. This derives directly from the general (yet often misunderstood) risk management principle:

If it's risky to not secure, DO secure (e.g., uncertain, high loss potential, unprecedented);

If it's risky to secure, DO NOT secure (e.g., well-established, well-known, highly tested, robust).

(Boehm 1991)

The above principle provides a simple rationale for balancing $RE_{security}$ and $RE_{usability}$ and determining an effective amount of security *before* committing to a particular security strategy. Assuming we have generated a strategic $RE_{security}$ profile as described in the section on “Multitechnique Strategic Methods,” then the optimal effort

to expend will be where $RE_{security} + RE_{usability}$ is minimal. Although we know there are many dependencies among these risk factors, we are taking advantage of the remarkable previously mentioned fact that the REs are additive. As shown in Figure 7a, the decreasing $RE_{security}$ and increasing $RE_{usability}$ will have a minimum—the “sweet spot” at some intermediate point of effort. As a result of our risk-management principle, a strategic stopping point for the security effort is when this intermediate point has been reached. The sweet spot determination for the examples discussed in Figure 5 and Figure 6 is shown in Figure 7b. In this case, the purely cost-benefit analysis would recommend stopping security efforts at step T_4, however, accounting for $RE_{usability}$ indicates that T_3 is a more strategic stopping point.

The location of the sweet spot will vary by type of organization. For example, for the network in an internet service provider (ISP) in which $RE_{usability}$ increases rapidly because of high usability needs (e.g., market pressures and demanding customers with diverse needs), results in a sweet spot pushed to the left, indicating that less security effort should be expended. In contrast, a security-critical network, such as for a bank will have greater $RE_{security}$ because of larger potential losses. The sweet spot is pushed to the right, indicating that more security should be done. This is illustrated in Figure 7a.

Unsuitable Sweet Spots

There are situations in which the sweet spot is not an acceptable determination of how much assessment to perform. Acceptability is achieved only when (as indicated in Figure 7a) the RE at sweet spot is below a given risk tolerance and the effort at the sweet spot is less than the effort at critical point 3. Although, ideally, the assessment effort should be less than the effort at point 1, for most projects the additional risk incurred by passing this point is tolerable (Basili and Boehm 2001). In our example in Figure 7b we see the sweet spot is well past point 2. Because critical point 2 is where users have already begun reporting usability issues, depending on an organization's goals and policies, this may be unacceptable.

In Figure 7a there is an indication of an acceptable risk tolerance level, and the sweet spot lies below this level. What can be done if it lies above the acceptable risk tolerance level? There are two solutions: find another security approach (e.g., more cost-effective techniques) that can

Figure 7: (a) Balancing $RE_{security}$ and $RE_{usability}$. (b) Sweet spot for example

lower RE_{security} or mitigate potential losses due to usability (e.g., user training, faster hardware) in order to lower $RE_{\text{usability}}$. It is best if both approaches are applied simultaneously. If the sweet-spot effort exceeds the effort for point 2, the only reasonable approach is to find another security approach that can lower RE_{security} more quickly or reconsider the organization's policies. Paradoxically, if $RE_{\text{usability}}$ were increased, say by imposing greater cost, schedule, or effort constraints, this too could potentially move the sweet-spot effort in front of point 2. However, the price to pay for this is a heavy increase in the overall risk, which likely will exceed the tolerable level.

PRACTICAL RISK EXPOSURE ESTIMATION

A risk-management program relies critically on the ability to estimate representative risk exposures. It is tempting to expend a large amount of effort to obtain precise results; however, this may prove untenable or impractical. Fortunately, for strategic method applications estimates do not have to be precise. In this section we will describe one practical approach to estimating risk exposures.

Qualitative Methods

Recall that calculating RE for a given risk involves estimating the probability of a potential loss $P(L)$ and the size of that possible loss $S(L)$. The challenge of estimating $S(L)$ lies in quantifying intangibles such as "loss of reputation." There are numerous techniques that claim the ability to address this challenge; however, we have found that estimating highly subjective loss potentials is best accomplished by choosing a tangible "standard" within the particular context at hand and then establishing the remaining values relative to this standard. For example, an organization determined that because of lost sales they lost \$1,000 for every minute their central sales system was down. If the sales system was down for more than 4 hours, their reputation as an "easy to buy from" company would be degraded and fewer customers would return. The minimum loss of $4 \times 60 \times \$1,000 = \$240,000$ was considered a "3" on a scale from 0 to 10 in terms of loss magnitude, and the loss of return customers was considered a 5 relative to this monetary loss. These size estimates can be used for RE calculations so long as all loss potentials are translated into loss magnitudes from 0 to 10 relative to the system down time.

In general it is difficult to calculate $P(L)$ directly. This is primarily due to a lack of representative models that are able to generate an appropriate probability distribution. Even though there are many wonderful candidate parameter-based models, frequently there is not enough available data to calibrate and validate them.

One alternative to parametric models is to make use of a qualitative "betting analogy" as described in the following steps:

Step 1: For the risk under consideration, define a "satisfactory" level.

Step 2: Establish a personally meaningful amount of money, say, \$100.

Step 3: Determine how much money you would be willing to risk in betting on a satisfactory level.

Step 4: Establish a proposition (e.g., Using a virus checker will avoid infection and loss of data).

Step 5: Establish betting odds (e.g., No loss of data: you win \$100; infection and loss of data: you lose \$500).

Step 6: Determine willingness to bet:

Willing: low probability

Unwilling: high probability

Not sure: there is risk due to uncertainty, so need to buy information

Express your willingness to bet with respect to the risk under consideration

e.g. We are likely to take this bet

For whatever qualifies your willingness-to-bet statement (in our example the qualification is "likely," use an adjective calibration chart such as the one illustrated in Figure 8 to get an estimate of the risk probability.

Empirical Approaches

Empirical methods rely on generating risk-exposure estimates based on observations, historical data, or experiments. One of the attractive properties of risk exposure is that it represents the expectation (or mean value) of the potential losses associated with a risk event. Under quite general conditions, this value can be approximated with the sample mean. Say you have losses $L_1, L_2, \dots, L_n$ associated with a particular risk area, then

$$RE \approx \frac{1}{n} \sum_{i=1}^n L_i$$

Consult any college-level statistics book for further details on this. We can make use of this result in several ways, depending on whether or not historical risk loss data and risk event models are available. Historical risk loss data is the recorded losses realized from actual projects that were exposed to the risk (i.e., the risk actually occurred) under consideration. A risk-event model is a dynamic representation of all the possible losses and conditions under which those losses would occur.

Delphi Studies: No Historical Data, No Risk-Event Model

You may have noticed that the betting analogy relies on having a credible adjective-calibration table. These tables might have been based on surveying local experts. This technique can be used directly to estimate risk exposures. If a representative group of experts are available, a *Delphi study* (Helmer 1966) often provides workable risk-exposure estimates. Such a study would survey experts to estimate risk-exposure values and then calculate the sample mean as an estimate for the actual risk exposure. To avoid getting erroneous results, Delphi studies should not be undertaken haphazardly. There are a variety of well documented methods for conducting Delphi studies that should be followed to ensure valid results.

Figure 8: Probability adjective calibration table (what uncertainty statements mean to different readers)

Risk Sampling: Historical Data Available, No Risk-Event Model

If there is a reasonable amount of historical loss data available that is representative (unbiased) then risk sampling may be an effective means of estimating risk exposures. Calculate the estimated risk exposure by taking the sample mean of the historical data. However, it is likely that the data set will be small and the estimate may be poor. Under these conditions, bootstrapping and jackknifing methods (Effron and Gong 1983) may be used to improve estimates.

Risk-Event Simulation: No Historical Data Available, Risk-Event Model Available

When historical data are lacking (or nonexistent) and you are able to model the particular risk events under consideration, then risk-event simulation may provide a means of estimating risk exposures. Usually this amounts to creating a series of random events to run through the risk model and then calculate the sample mean to estimate the risk exposure. The idea here is to create a dynamic simulation of the risk events and run a series of experiments to get a representative collection of loss values. There are a host of powerful tools that can be of great use in creating and running these simulations. Two examples are the Simulink package for Matlab (www.mathworks.com) and also Modelica for Dymola (www.dynasim.com).

Pitfalls to Avoid

As indicated in the above discussions, there are many possible complications in estimating risk exposures, such as using insufficient or biased data. Of all the potential complications, perhaps the most common and troublesome is the problem of *compound risks*—a dependent combination of risks. Some examples are:

- Addressing more than one threat
- Managing threats with key staff shortages

- Vague vulnerability descriptions with ambitious security plans
- Untried operating system patches with ambitious release schedule

You must watch out for compound risks. The problem is that the dependencies complicate the probabilities in difficult-to-determine ways. When you identify a compound risk, it is best to reduce it to a noncompound risk, if possible. If the dependencies are too strong or complex, then this may not be possible. In this case you should plan to devote extra attention to containing such risks.

CONCLUSION

In this chapter, we have shown a number of network risk assessment and management techniques. This is a rich and growing field of inquiry, and it reaches deep into technical as well as organizational and managerial practices. The key insights that the reader should take away from this chapter are that: (1) network risk management is effective only to the degree that risk assessment is effective; and (2) it is not obvious how to go about applying individual security techniques (of which there are many) to ensure an optimal result at the level of the organization.

To address these issues we have described and demonstrated a strategic method for quantitatively assessing network risk that is probably optimal with respect to cost-benefit. This gives a manager a powerful tool for managing network risk.

GLOSSARY

FRAP: Facilitated Risk Assessment Program

OCTAVE: Operationally Critical Threat, Asset, and Vulnerability Evaluation

Risk: Possibility of loss or injury; a situation or event that can cause a project to fail to meet its goals

Risk Assessment: A set of activities aimed at quantifying the level of risk, consisting of risk identification, risk analysis, and risk prioritization.

Risk Control: A set of activities aimed at managing overall project risk, consisting of risk management planning, risk resolution, and risk monitoring

Risk Exposure: A quantification of the damage due to a risk, calculated as the product of the probability of a loss and the size of the loss, e.g., $RE = \text{Prob}(\text{loss}) * \text{Size}(\text{loss})$

INTRODUCTION

A computer network is deemed “reliable” when it has the ability to continue operations in spite of a disruption, regardless of the cause, while resources affected by the disruption are restored. Network reliability planning is the practice of prioritizing and assigning dollars to those portions of the network that are most mission-critical and whose interruption can directly affect service delivery. If not done properly or done indiscriminately, network upgrades intended to improve reliability can in fact be wasteful and could lead to ineffective solutions that produce a false sense of security. This is why an understanding of some basic reliability concepts is often the practitioner’s best tool in planning and designing network upgrades to improve survivability and performance, without becoming overwhelmed by today’s vast array of network technologies.

To this end, this chapter reviews some basic principles behind network reliability and fault tolerance. Although many of these concepts have been around for quite some time, in the past several years they have become more dominant in the planning and design of network infrastructure. Many of the concepts discussed here arose from developments in telecommunications, the space program, and the nuclear industry. They are applicable at almost any level of a network infrastructure—from component to network service, from software to hardware, from topology to operations. When used collectively and coupled with human judgment, these concepts can be an invaluable tool to characterize and understand network survivability and performance. More detailed discussions of many of these concepts can be found in Liotine (2003).

FUNDAMENTAL PRINCIPLES

Disruptions in a network operation occur mainly because of lack of preparation. Inadequacy in planning, infrastructure, enterprise-management tools, processes, systems, staff, and resources typically fuel disruption. Poor

training or lack of expertise can lead to human error. Process errors result from poorly defined or documented procedures. System errors such as hardware faults, operating system hangs, and application failures are inevitable, as well as power outages or environmental disasters. Disruptions produce *down time* or *slow time*—periods of unproductive time resulting in undue cost. The conditions that lead to disruption can comprise one or many unplanned circumstances that could ultimately degrade a system to the point at which its performance is no longer acceptable. *Up time* is the opposite of down time; it is the time when an operation is fully productive. The meanings of up time, down time, and slow time are a function of the context of the service being provided. Many e-businesses view up time from the end user’s perspective. Heavy-process businesses may view it in terms of production time, while financial firms view it in terms of transaction processing.

When a disruption occurs, several activities must take place (see Wrobel 1997):

- *Detection* is the process of discovering a fault, latent fault, or problem, after it happens or in advance. Quite often, a hidden problem can go undetected for a time, increasing the potential for damage. The longer it takes to discover a problem, the greater the possibility of extensive damage and increased recovery cost. Fault-detection mechanisms recognize certain behavioral patterns that forewarn that a fault has or is about to occur. Accurate fault detection involves reporting faults in a way that discriminates, classifies, and conveys priority. Valid faults should be distinguished from alerts stemming from nonfailing but affected devices. Although such accuracy may improve system reliability, it can also incur greater expense.
- *Containment* is the process that controls the effects of a disruption so that other systems are unaffected and end-user impact is minimized.
- *Failover* is the process of switching to a backup component, element, or operation while recovery from a

Figure 1: Network recovery processes

disruption is undertaken. *Hot* or *immediate failover* normally requires a running duplicate of a backup system to provide immediate recovery. *Cold failover*, on the other hand, uses a backup element with little or no information about the state of the primary system and must begin processing as if it were a new system upon failover. *Warm failover* uses a preinitialized backup that is not necessarily provided with all of primary system state information until a failover takes place.

- *Repair* is the activity of fixing a problematic component or system. Repair activity may not necessarily imply that the element has been returned to its operational state.
- *Contingency* is the activation of a backup element or process upon failover from the primary failed element. It can represent a backup component, system, network link or path, service provider, recovery data center or hot site.
- *Resumption* is the process of returning the repaired element back into operational service. It is the process of transferring operations over to the restored element, either gradually or instantaneously.

Figure 1 illustrates how these processes interact in relation to an adverse event. A detection process will identify that a network outage has occurred, or is about to occur. Once this happens, a failover process is invoked to activate and continue processing on a contingent network or system. While this is occurring, the process to contain and repair damaged systems is conducted. When this is completed, the resumption process gradually migrates the repaired components back into operation.

NETWORK TOLERANCE

Tolerance is the ability of an operation to withstand problems, whether at the component, system, application, network, or management level. Tolerance is often conveyed as *availability*, or the percentage of the time that a system or operation provides productive service. For example, a system with 99.9% (or three 9) availability will have about 8.8 hours of downtime per year. A system with 99.99% (or four 9) availability will have about 52 minutes of downtime per year. (Availability is discussed later in this chapter.) There are three general classes of tolerance

often used to characterize computing and communication platforms, and are applicable to almost any level of network operation:

- *Fault tolerance* is a network's ability to automatically recover from problems. For this reason, it is usually associated with availability in the range of four to five 9s (or 99.99% to 99.999%). Such systems are designed with hot failover mechanisms, so that a single fault will not cause a system failure, thereby allowing applications to continue processing with virtually no transaction loss. It is typically achieved through component redundancy, continuous error checking, and automatic failover and recovery mechanisms.
- *Fault resilience* is used to characterize systems with availability of about four 9s (or 99.99%). A fault-resilient operation does not necessarily guarantee no transaction loss. It is usually achieved through warm failover mechanisms.
- *High availability* is typically associated with availability in the range of 99.5% to 99.9%. Here, the expectation is that some transactional loss will occur during failover. Reliance on higher-level resources is typically expected to minimize disruptive impact.

As one might expect, fault-tolerant systems and operations are typically the most expensive to implement, and are usually found in mission-critical network applications, such as those involved with telecommunication and military operations. Critical factors in deciding the appropriate level of tolerance for an implementation are often cost and how problem correction and resolution are automated and allocated across network components.

NETWORK PROTECTION

Network protection is generally achieved by establishing redundancy through design and operation. Although multiple paths between critical network nodes could provide alternative routes for traffic to traverse if one path is congested or lost, the surviving path should have adequate capacity to handle the diverted traffic. Similarly, nodes or systems that are replicated for improved reliability but share common connectivity, infrastructure, or resources can be vulnerable to the same outage within those

Figure 2: kN redundancy

elements. These scenarios typify false redundancies, which can artificially inflate network capital and operating costs while not providing additional levels of protection. In the end, protection must be applied appropriately and to those elements of the network infrastructure that are considered mission-critical. Concepts from graph theory such as two-terminal reliability, graph transformation, node-pair resilience and spanning trees have been used to intensively model communication networks, fault tolerance, and reliability (see Shooman 2002). Such concepts form the basis for much of the discussion that follows.

Redundancy

Redundancy is a network architectural feature in which multiple elements are used so that if one cannot provide service, the other will. Redundancy can be realized at many levels of a network in order to achieve service continuity. Network access, service distribution, alternative routing, system platforms, recovery data centers, and storage all can be instilled with some form of redundancy. It can also involve the use of redundant service providers, suppliers, staff, and even processes. Redundancy should be applied to critical resources required to run critical network operations. It should be introduced at multiple levels, including the network, device, system, and application levels.

Redundancy is best used to eliminate *single points of failure* (SPOFs). These can be any single isolated network element or resource that upon failure can disrupt a network's productive service. Fundamentally, redundancy involves using multiple elements to perform the same function as the SPOF. There are two fundamental types of redundancy that are often used, depending on the cost and level of need, where N is the number of resources needed to provide acceptable performance:

- kN redundancy, as illustrated in Figure 2, replicates N resources k times (i.e., $2N$, $3N$, $5N$, etc.). For example, if one ($N = 1$) network switch is sufficient to handle all network traffic, then $2N$ redundant network switches allow one switch to continue switching traffic if the other fails or becomes isolated.

Figure 3: $N + K$ redundancy

- $N + K$ redundancy, as illustrated in Figure 3, involves having K spare resources for a set of N resources. If one of the N resources is removed, fails, or degrades, then one of the K spares takes over. For example, if a network requires 4 switches ($N = 4$) to process all traffic, then a network can be configured with 5 switches ($K = 1$) so that losing one switch does not affect service.

kN redundancy enables concurrent error detection and possible correction versus $N + K$ redundancy. $N + K$ arrangements can also be used in conjunction with kN arrangements, offering different granularities of protection. A kN arrangement can have K sets of resources, each having an $N + K$ arrangement to ensure a higher degree of reliability within a set.

NETWORK FAILURE

Networks are exposed to many types of threats. A threat can represent a broad range of adverse events that can produce damage, such as lost assets, productivity, or missed earnings or sales. Risk is the expected monetary loss or damage resulting from a particular threat. The greater the risk posed by a threat, the more important it becomes to mitigate that threat. A condition or event that could create much damage but has little chance of occurring can yet pose substantial risk if a network is not well protected against it. Threats can arise from all kinds of sources, typically human-made (e.g., mistakes, errors, design oversights, etc.), machine-made (e.g., breakdowns), and natural (e.g., weather, earthquakes, etc.). The nature

of potential failures posing threats must be well understood in order to assess the reliability of a network.

Failures are adverse conditions that individually or collectively lead to delayed or immediate service disruption. *Self-healing failures* are those that are immediately correctable and may not require intervention to repair. Although they may have no observable impact on a system or operation, it is still important to log such instances, since they could conceal a more serious problem. *Intermittent failures* are chronic errors that often require some repair action. Persistent intermittent errors usually signal the need for some type of upgrade or repair.

Failures that occur in single isolated locations, components, connections, or some other piece of infrastructure are referred to as *simplex failures*. When not addressed, simplex failures can often create a chain reaction of additional failures, cascading into other network elements. These are referred to as *rolling failures* or *cascading failures*, often characterized by unsynchronized, out-of-sequence events that ultimately can be the most damaging.

Identifying a fault or problem in a network service often requires correlating information across different events or conditions at different network levels. Alarms or alerts might arise from individual or several devices or nodes, or perhaps no information is conveyed from a failing device. This latter case is sometimes referred to as a *fail-silent* fault model, in which a device will cease operating without communicating failure information to other devices. In emerging networks, transmissive fault models have become more prevalent. These involve dissemination of information among internal and external network devices. A *symmetric* fault is one that affects other devices in the same manner or conveys the same information to them. More common is the *asymmetric* fault, in which devices are not affected equally or are not given the same or correct information. Consequently, such faults are often more difficult to diagnose and require more information correlation. The following sections describe some fundamental parameters that are often used to characterize network failures.

Mean Time to Failure

Mean time to failure (MTTF) is the average time between placing a system or component in service until it fails. Ideally, to calculate MTTF accurately requires a system to be monitored for its expected useful lifetime, which can be quite long. Whether estimation of the MTTF involves monitoring a system for several years or a hundred years, accurate MTTF computation is often impractical to

obtain. MTTF is viewed as an elapsed time. If a network element or system is not used all the time, but say at a periodic rate (every day only during business hours, for example), then the percent of time it is in operational use (or duty cycle) should be factored into the estimation.

Failure Rate

A *failure rate* is defined as the frequency of failure in terms of failures per unit time. System vendors might often state failure rates in terms of percent failures per 1000 hours, and will often use statistical sampling methods to estimate average failure rates over large populations of components. A failure rate can also be stated as $1/\text{MTTF}$. In general, the failure rate conveys a system's propensity for failure over its operational lifetime. Many failure-estimation techniques assume an exponential distribution, in which the failure rate is constant with time.

Mean Time between Failures

The mean time between failures (MTBF) is a metric that conveys the mean or average life of a system, based on the frequency of system failures (see McCabe 1998). It is the average time between failures over the system's or network's operational life. It is somewhat different from MTTF, although the two are quite often used interchangeably. For example, if a system experiences 3 failures in 1000 hours of operational time, then the MTBF is approximately 333 hours. However, each failure may have occurred after 330 hours of operation, assuming a mean time to recovery (MTTR) of 3 hours. Figure 4 illustrates this relationship. MTTR is discussed further in this chapter.

The MTBF for a system or network can be estimated in various ways. If the MTBF is estimated as an arithmetic mean of observed MTBF values across numerous network nodes or systems, one could assume that MTBF represents the point in time at which approximately half of the systems have had a failure, assuming failure times are normally distributed (see Dooley 2002). Figure 5 illustrates the use of this assumption. For a network with a population of N nodes or systems, the MTBF would represent the median observed failure time. If the distribution of failure times is normal, this time would also convey the time corresponding to $N/2$ (or 50%) of the observed failure times. So, for example, in a large network with an estimated MTBF of 10 years, one would expect on average about half (or 50%) of the devices to have failed during that period, or 5% a year on average ($50\% \div 10$ years).

Figure 4: Relationship between mean time to failure (MTTF), mean time to recovery (MTTR), and mean time between failures (MTBF)

Figure 5: Failure approximation using MTBF

NETWORK RECOVERY

Recovery is comprised of all the activities that must occur from the time of an outage to the time service is restored. These will vary among organizations and depending on the context of use within a network environment. General recovery activities include declaration that an adverse event has occurred (or is about to occur), initialization of a failover process, repair activities, system restart, cutover, and resumption of service. It is important to distinguish between two types of recovery. *Service recovery* is the point at which a network continues to provide service, but not necessarily in the same way it did prior to an outage, yet in a manner that is satisfactory to end users. In this case, service is restored even if a problem has not been fixed. *Operational recovery* is the point at which a network delivers service in exactly the same fashion prior to the outage. The following sections describe some fundamental parameters that are often used to characterize network recovery operations.

Recovery Time Objective

The recovery time objective (RTO) is a target measure of the elapsed time interval between the point at which a disruption occurs and the point at which service is resumed. RTO is typically specified in units of time (hours, minutes, seconds, etc.) and represents an acceptable recovery time. The RTO can be applied to any network component—from an individual system even to an entire data center, depending on the case at hand. To define an RTO, one must determine how much service interruption can be tolerated. RTOs are usually in the range of 24 to 48 hours for large systems, but these numbers do not reflect any industry standard. Recovery cost is ultimately a deciding factor in determining an RTO objective. A high cost is required to achieve a low RTO for a particular process or operation. For example, to achieve an RTO close to zero would likely require expensive automated recovery and redundancy. As the RTO increases, the cost to achieve the RTO decreases. An RTO of long duration, while less expensive, invites greater transactional loss.

Figure 6: Relationships between RTO and cost

This relationship is illustrated in Figure 6. Here, the cost curve represents the cost of implementing a recovery solution versus the target RTO. Although the technology and operations costs to produce a corresponding solution decrease as the target RTO grows in size, outage losses will tend to accumulate. The point at which the two curves intersect represents that at which the investment in solution costs would be completely recaptured by way of recovered losses. Investments made prior to that point could be viewed as overspent relative to the small amount of recovered monetary loss, while those made beyond that point might be considered underspent, unless the monetary loss entailed is acceptable to an organization.

Specifying an RTO can be somewhat difficult, since a network recovery can involve many activities. An RTO specified for an entire network operation should account for all such activities. As an alternative, component activities can each be assigned their own RTO. Nevertheless, an RTO should include the time to detect and declare an adverse event, as the detection time interval can play a major role in the overall recovery effort.

It is important to distinguish between service and operational recovery to better characterize and analyze recovery viability. For this reason, recovery objectives should be specified at several levels. The recovery access objective (RAO), for example, is the tolerable time interval for failover to a redundant resource that provides the same application or service. It will typically be much lower than an RTO, sometimes on the order of seconds. This is in effect the tolerable disruption time from the end user's perspective, and characterizes service recovery. This distinction is important, since although failover mechanisms might enable reasonable continuation of service from the end user's perspective, full recovery is not achieved until a downed resource is restored to operation.

Recovery Point Objective

The recovery point objective (RPO) is used as a target metric for data recovery. It is the maximum tolerable elapsed time between the last safe data backup and the time of resumption. It is measured in terms of time, and refers to the maximum age of data required to restore operation following an adverse event. Data, in this context, might also include information regarding transactions not

Figure 7: Relationship between RTO and RPO

recorded or captured during the outage. Like RTO, the smaller the RPO, the higher the expected data recovery cost. The RPO is the point in time to which the data must be recovered—sometimes referred to as the “freshness window.” An organization that can tolerate no data loss (i.e., $RPO = 0$) requires their data to be restored instantaneously following an adverse event, implying the need for some type of continuous backup system.

RTO and RPO are loosely related to each other, as illustrated in Figure 7. Specifying an RTO that is short in duration does not necessarily imply a short RPO. For example, although a system can be restored with working data within an RTO of an hour following an adverse event, it could yet be acceptable for data to have an RPO of, say, four hours.

Mean Time to Recovery

Mean time to recovery (MTTR) is sometimes referred to as mean time to repair or restore. In either case, it conveys the average time required to restore operation in a network service or component that has stopped operating, or is not operating to satisfactory performance levels. It includes the total time it takes to restore the component to full operation. It could include things such as diagnosing a problem, repairing or replacing a faulty element, and system restart. MTTR is expressed in units of time. The time to diagnose can typically present the most uncertainty in estimating MTTR and can thus have a profound effect on MTTR, and ultimately, system availability. When inverted, $1/MTTR$ can be used to characterize a restoration or recoverability rate of a service or operation.

NETWORK RELIABILITY AND AVAILABILITY

Reliability is the probability of failure over time. In some applications, it is often characterized conversely as the likelihood that a system will continue to provide service without failure. *Reliability* is often used interchangeably with *availability*, but the two are quite different, as will be evident from the following discussion. *Availability* is concerned with the percent of time a network resource can provide operational service. So, for example, a network service that provides 99.99% availability may on the surface seem reliable. However, no implications can

be made about the reliability of the service without considering the amount of failures experienced. In this case, while this availability level implies about 52 minutes of cumulative down time per year, there is no information regarding the number of failures that comprise this down time. Thus, this down time could have been the result of 3120 failures or service interruptions of one second each. In today’s real-time-data-driven environment, interruptions of such short duration and volume could be quite destructive. End users typically require continuous access to uninterrupted network services. The following sections discuss these concepts in greater depth.

Reliability

Reliability is the probability that a system will work for some time period t without failure (see Blanchard 1981). The classic expression for reliability is given by:

$$R(t) = \exp(-t/MTBF) \quad (1)$$

where $R(t)$ is the reliability of a system at time t . This function assumes that the probability that a system will fail by a time t follows an exponential distribution. Although this assumption is commonly used in many system applications, there are a number of other well-known probability distributions that have been used to characterize system failures. Reliability at any point in time t is essentially the percent probability that a system with a particular MTBF will operate without a failure, or the percent of the systems that will still be operational at that point in time. Figure 8 illustrates the reliability function over time. The reliability, or probability that a system will not encounter a failure, decreases with time. As shown in Figure 8, this decrease is less pronounced for systems characterized by higher MTBFs.

Reliability block diagrams (RBDs) are a tool used for computing the reliability of a complex system or network of systems. Applying the laws of probability, a serial relationship between system reliabilities in a network of systems, or components within a system, implies that the system is operational only when all components are operating. Consequently, an upgrade that places an additional network component in series with others can actually reduce overall network reliability. When network components or platforms are connected in series, the overall system reliability could be reduced because it is the product of component system reliabilities (see Oggerino 2001).

Figure 8: Reliability function over time

If the system or network is operational if either component is operating, then a parallel relationship is made. From the laws of probability, parallel reliability is obtained by subtracting from 1 the probability that all parallel components fail. Mathematically, this is done by multiplying the unreliability of each parallel component and then subtracting the result from 1 to obtain the reliability (see Hecht 2004). The following are the general formulas used to convey both the serial and parallel relationships for systems having N components:

Serial relationship (systems in series):

$$R(t) = \prod_{i=1}^N R_i(t) \quad (2)$$

Parallel relationship (systems in parallel):

$$R(t) = 1 - \prod_{i=1}^N [1 - R_i(t)] \quad (3)$$

Figures 9 and 10 illustrate example RBDs for these relationships. These relationships can also be used to assess the impact of kN and $N+K$ arrangements as well. To calculate reliability for systems with components having a mix of parallel or series relationships, a recommended approach is to first calculate parallel reliability for the parallel components, and then combine these results in serial to compute the reliability of the serial components.

Figure 9: Serial relationship using reliability block diagrams

Figure 10: Parallel relationship using reliability block diagrams

Although this approach can work fairly well to evaluate RBDs for a system or network in which the component interactions are clear, it can become impractical when trying to model very large complex systems with many interactions. Alternative approaches can involve using statistical models, such as Markov chain models. These models, however, can be limited also by the numbers of components and operational or failure states of the network. A more popular approach is network simulation, which requires building a computerized model of a network, reflecting the network's topology and operations.

Availability

Availability is the probability or percent time that a system or network can provide service. The availability, A , of a system or component is calculated by the following:

$$A = \text{MTTF}/(\text{MTTF} + \text{MTTR}) \quad (4)$$

Consequently, the unavailability of a system or component is given by $1 - A$. As is often the case, obtaining the precise MTTF from system vendors for a particular network device can be difficult. In some cases, the MTBF can be more obtainable from either system vendors or field data. In such instances the MTBF can be used instead of the MTTF. Although this may not be totally accurate, in the end it makes little difference in the availability calculation (see Oggerino 2001). In this case, the expression to compute availability is:

$$A = \text{MTBF}/(\text{MTBF} + \text{MTTR}) \quad (5)$$

Figure 11 illustrates the effect of MTTR on availability. Availability is significantly affected by system or network recovery procedures. Since decreasing the MTTR can have a profound effect on improving availability, any improvement that can reduce the MTTR can in turn improve overall network availability. A high MTTR is usually indicative of the need for some kind of network redundancy or back up system.

Since the value A characterizes a probability, the serial and parallel relationship rules can be applied to multiple systems in the same fashion as calculating reliability. The relationship of availability among systems can be generalized in the same way as was the case for reliability.

Figure 11: Effect of MTTR on availability

Thus, for a network or system having N components, the following formulas can be used:

Serial relationship (systems in series):

$$A = \prod_{i=1}^N A_i \quad (6)$$

Parallel relationship (systems in parallel):

$$A = 1 - \prod_{i=1}^N (1 - A_i) \quad (7)$$

Furthermore, for multiple systems or components, availability block diagrams (ABDs) can be constructed in the same manner as RBDs. Figures 12 and 13 illustrate example ABDs for these relationships. Although these resemble the RBDs that were discussed earlier, the RBDs were shown as time-dependent relationships.

Figure 14 shows a hypothetical example illustrating the effect of redundancy on availability. The example shows a Web site network configured with and without parallel server redundancy. By adding a second server in parallel to the first, as one might do in a cluster configuration, down time is significantly improved. It should be stressed that adding parallel redundancy to systems with low availability rates has greater impact than adding redundancy to systems that already have high availability. On the other hand, improving the availability of

Figure 12: Serial relationship using availability block diagrams

Figure 13: Parallel relationship using availability block diagrams

Availability:

Total availability = 98.8%
Annual downtime = 105 hours

Availability with cluster:

Server cluster
Availability = 99.99%
Total availability = 99.79%
Annual downtime = 18.4 hours

Figure 14: Example of availability

Figure 15: Cost versus availability

individual parallel systems can only marginally improve overall network availability.

Organizations will typically define their desired levels of availability according to the severity and impact on operations. The information technology industry has grown to recognize several known levels of availability. For example 99.999% availability is the typical standard for public switched telecommunication networks. This means, for example, that there could be one failure during a year that lasts just over five minutes, or there can be five failures that last one minute each; 99.5% is considered high availability, while 99.9% is often used for storage systems. Availability at 99.99% is considered fault resilient for reasons cited earlier.

Fundamental to achieving availability is the law of diminishing returns. The higher the level of availability, the greater is the cost of achieving a small improvement. A general rule of thumb is that the cost doubles to achieve each additional nine after the second nine in an availability value. Thus, for example, if the cost to achieve 99.9% availability was \$250,000, then the cost to achieve 99.99% availability will likely be \$500,000. As illustrated in Figure 15, improvements in availability diminish as one approaches 100%. Thus, achieving 100% availability is theoretically cost prohibitive—there is only so much availability that can be reasonably achieved.

Network Design Considerations for Reliability

Greater availability in a network can be achieved in several ways. First, improvement in recovery operations can help minimize down time, and consequently improve overall availability from the end user's perspective. Second, the availability of individual systems in a network can be improved through system upgrades, possibly bringing them to the level of fault-tolerant systems, as in the case of telecommunication networks. A third approach, which can be used in combination with the previous approaches, is to strategically place redundant systems or elements in parallel operation within the same network. By doing so, the percent of time the network is available is then equivalent to the percent of time either or both systems are operating. In each case, the effect is to keep the duration of outages as short as possible and reduce the overall MTTR, so that end users have uninterrupted access to service.

In the sections that follow, we will address some additional things that should be considered when planning availability improvements within a computing network. Specifically, we will discuss how network architectures and protocols can be leveraged to improve overall network survivability. A network architecture defines the ways in which nodes or elements of a network are interconnected. The links between nodes are governed by layered communication protocols. Inadequate network design and protocol recovery processes could further promote the potential for outages.

Network Architecture

Additional reliability can be manifested within a computing network through its architecture. The topology should be such that redundant paths or links lie between critical network nodes, at both the logical and physical layers. Even at this level of the network, the redundancy principles previously discussed can still apply. A redundant link design provides at least one alternative link between nodes so that information can be transported between them if a primary link fails. The protection can be achieved by duplicating the link over the same layer, creating a secondary link at a lower layer, or by creating completely different links using different physical or logical layers.

Protecting a path can be more complex than protecting a single link, since it implies more recovery intelligence in network elements. If a protection path is required, it is important to decide whether to define that path or route in real time (i.e., immediately after failure) or in advance. When paths are defined in real time, it implies that the network technology in use is focused primarily on maintaining connectivity in the event of a failure. An example of this is use of spanning tree protocols used in switches to compute multiple paths through a local area network (LAN), or open shortest path first (OSPF), used to compute multiple paths through a complex Internet protocol (IP) network. In such cases, it can take an inordinate amount of time to compute alternative paths in real time, depending on the protocol in use. Using preconfigured paths can better ensure performance levels, since these paths can be traffic-engineered beforehand. The multiprotocol label switching (MPLS) protocol, in fact, makes use of this capability (see Xiao et al. 1999).

The ability to define paths in a network, either statically or dynamically, is premised on whether the network topology can facilitate alternative path arrangements. Multiple paths are often appealing to further ensure reliability. However, such redundancy comes at a price, requiring design trade-offs between complete network connectivity and a hub-like structure. Quite often, greater network path redundancy will entail greater costs. For example, well-known topologies such as the *mesh* and *ring* each have survivability and protection characteristics. Mesh topologies are the most robust in eliminating SPOFs, since every node is connected to every other node to some degree, so that many alternative traffic routes can be defined. However, mesh networks are typically the most expensive to build. Ring topologies, on the other hand, are used as a less expensive option since they can

Figure 16: Examples of network SPOFs

Figure 17: Example of a tiered network

protect against node and link failures as long as there is adequate link capacity to support redirected traffic. Figure 16 illustrates these points. Such is the case with synchronous optical network (SONET) and resilient packet ring (RPR) architectures.

Most computing networks are made up in a tiered fashion, with each tier using different types of topologies. Figure 17 illustrates a common tiered architecture that is often used in constructing a reliable network infrastructure. A sound approach to implementing network survivability is to optimize each tier for reliability as well as the connectivity between tiers. As traffic is aggregated going up the tiers, switches grow larger in capacity and require greater port utilization. Consequently, failures in either switches or links in the higher tiers can have more far-reaching effects. As a general rule, network links should be engineered to accommodate both their working traffic as well as additional traffic that is displaced should an outage occur.

The edge network is the access portion that connects remote end points, typically end users or other networks, to a main network. The edge network is usually the most vulnerable portion of a network. Efforts to improve the reliability of a network can be ineffective if the edge network is isolated in the event of a failure. Because edge nodes aggregate traffic onto a backbone network, they can be potential SPOFs if left unprotected. For example, if the edge network is home to a large number of LAN users who connect to a wide area network (WAN) or Internet through a switch or router, failure of that device or link can be catastrophic. Figure 18 illustrates this concept. A local network connecting to a WAN through one

Figure 18: Example of an edge network

single device (a router) is immediately at risk, since that device is an SPOF. Failure of that device would prevent all local network user traffic from traversing the WAN.

Network Protocols

Computing networks rely on a multitude of protocols for their operation. There are numerous network protocols in use today, posing interoperability issues in using different systems and products. Extensive management coordination between the network protocol layers can introduce unwanted costs or resource consumption, as well as more network overhead. Network layer protocols usually have recovery features that come into play if a transmission link encounters high error rates or if a link or node fails. For example, reliability is important in each layer of open systems interconnection (OSI) and transmission control protocol/Internet protocol (TCP/IP) models. One will find many protocols in use across these layers and within these layers as well. Recovery requirements and inherent recovery mechanisms can vary widely across the many protocols and protocol layers depending on the type of network in which they are used. This phenomenon can often threaten interoperability and pose network vulnerability issues, raising the question as to how to provide proper protection at the right layers, yet avoid over protection or conflicting recovery mechanisms.

Use of a *parallel* strategy, which is quite common, simply allows every layer to apply its own protection or recovery mechanism. Although this can lead to overprotection, which can consume extra resources in other layers, it can also cause oscillations and unnecessarily throttle traffic. A general rule of thumb is to use a *sequential* strategy—that is, if a lower layer cannot provide needed protection, then apply protection at the next highest layer. Although this might seem like a sensible approach, survivability mechanisms between layers can yet create some undue problems. For example, if a physical link is cut between two switches, it is likely that layer 3 IP routing is unaffected, since recent strides in protocols, such as rapid spanning tree, can quickly reconstruct a spanning tree at layer 2. However, as IP switching times continue to decrease with improvements in technology, route oscillations could take place unless state information is exchanged between layers. This represents a *coordinated* strategy, a feature found in multilayer switching. Although this might seem like a sensible approach, it often can be difficult to achieve

across different vendor products unless a single product line is used (see Breyer and Riley 1999).

SUMMARY AND CONCLUSION

Network recovery involves the specification of the RTO and RPO. The RTO is a target measure of the time interval between an outage and full restoration. The RPO, on the other hand, is used to specify the desired age of data required to restore operation following a service interruption. The MTTR is an observed average measure of the time required to restore operation. Network and system failures are conveyed using the frequency of failures and the MTTF. The MTBF measures the average life of a network component. Thus, a low MTBF could imply greater maintenance costs.

Network reliability conveys the ability to continue service even if a system or network resource becomes inoperable. It is best achieved using a mix of redundancy, reliable systems, and good network management. Although adding redundant systems in parallel can significantly improve network reliability, adding components in series could actually reduce it. Availability is the proportion of time service is provided. Availability as a measure can conceal outage frequency, so it should be interpreted carefully. Although *reliability* and *availability* are often used interchangeably, the two will differ slightly. *Reliability* is suggestive of failure frequency, whereas *availability* is indicative of service duration. The availability calculations presented can be used to estimate the contribution of each component or resource to the overall availability of a network. Although these estimates can never be precise, they can be used to evaluate the relative value of upgrade alternatives, and can help flag the areas of a network that require more attention.

Network reliability is typically improved by eliminating SPOFs through system upgrades, network redundancy, and improved recovery practices. At the system level, upgrades can be made to improve both the reliability and availability of the individual systems that comprise network nodes. At the network level, redundancy can be added by placing redundant systems in operation and/or establishing multiple paths between systems. This requires choosing appropriate network topologies and protocols to facilitate system failover and traffic redirection. Finally, recovery practices should involve detection, containment, failover, repair, contingency, and resumption procedures that can respond to adverse network or system events. In the end, achieving network reliability is often more art than science, involving trade-offs between cost, systems, topologies, and protocols.

GLOSSARY

Asymmetric Fault: A malfunction that impacts other devices differently or conveys different or incorrect information to them.

Availability: The probability or percent time that a system or network can provide service.

Containment: The process that controls the effects of a disruption so that other systems are unaffected and end-user impact is minimized.

Contingency: The activity of activating a backup element or process upon failover from a primary failed element.

Detection: The process of discovering a fault or problem after it happens or in advance.

Down Time: The period of time when a network service or element is unavailable.

Fail-Silent Fault: A failure whereby a network device will cease operating without communicating malfunction information to other devices.

Failover: The process of switching to a backup component, element, or operation while recovery from a disruption is undertaken.

Failure Rate: The frequency of failure in terms of failures per unit time.

Mean Time Between Failures (MTBF): The average time between failures over the system's or network's operational life.

Mean Time to Failure (MTTF): The average amount of time between placing a system or component in service until it fails.

Mean Time to Recovery (MTTR): The average time required to restore operation in a network component that has stopped operating, or that is not operating to a satisfactory performance level.

Recovery: All the activities that must occur from the time of an outage to the time service is restored.

Recovery Access Objective (RAO): The tolerable time interval for failover to a redundant resource that provides the same application or service.

Recovery Point Objective (RPO): A target metric referring to the age of data required to restore operation following an adverse event.

Recovery Time Objective (RTO): A target measure of the elapsed time interval between the point in time when a disruption occurs until service is resumed.

Reliability: The probability that a system will work for a designated time period without failure.

Repair: The activity of fixing a problematic component or system.

Resumption: The process of returning a repaired element to operational service and transferring operations over to that element, either gradually or instantaneously.

Self-Healing Failure: A failure that is immediately correctable and may not require intervention to repair.

Single Point of Failure (SPOF): Any single isolated network element, component, or connection that upon failure can disrupt a network's productive service.

Slow Time: The period of time when a network service or element's performance is such that productivity is reduced to unacceptable levels.

Symmetric Fault: A malfunction that impacts other devices in the same fashion, or conveys the same information to them.

INTRODUCTION

Security is of prime importance for every business as security breaches can affect both a company's value and its reputation. The ever-rising need for business security leads to the development of new technological solutions on a regular basis. Companies often rely blindly on technology to eliminate as many risks as possible that occur in their work environment. Technology, however, leaves a gap; technical solutions are made by humans and administered by humans. The output of technical solutions is interpreted by humans. The entirety of these factors describes the biggest security issue: "the human factor" (Maris 2005).

Definition

Social engineering is a practice that may be used to exploit this "weakest link" in the security chain of an organization (Allen 2001). There are various definitions of social engineering contributed by different authors. Most of them agree that social engineering is an act of deceiving people into revealing private or otherwise confidential information or providing access to outsiders, sometimes called "hackers" or "crackers" (Allen subscribes to the common definition of "hackers" as interested people who don't intentionally inflict damage and "crackers" who set malicious actions). Social engineering can best be understood as "the art and science of getting people to comply to your wishes" (Harl 1997).

Following this argument, social engineering is not necessarily tied to technological aspects and settings;

salespersons and confidence men may be dubbed "social engineers" as well.

Kevin Mitnick, a well-known hacker and cracker, provides a more detailed definition:

Social Engineering uses influence and persuasion to deceive people by convincing them that the social engineer is someone she is not, or by manipulation. As a result, the social engineer is able to take advantage of people to obtain information with or without the use of technology. (Mitnick and Simon 2003)

For many, social engineering has an aura of mystery. Unlike technological tricks and tools, it is limited only by the hacker's imagination. The techniques take time to master and need a quick mind, practice, and intuition, especially when interacting directly with people. The efficiency of social engineering lies within people's perception that hackers master technology, not human behavior (Lafrance 2004).

Denning (2000) draws a line between technology and social engineering: "When they can't crack the technology, they use 'social engineering' to con employees into giving them access."

Motivation

What is the motivation behind social engineering? Once mastered, social engineering can be used to gain access on any system independent of the platform or the quality of hardware and software present. This also makes it the most

difficult form of attack to defend against because hardware and software alone cannot stop it (Arthurs 2001).

The danger of social engineering lies in people's unawareness concerning the topic. Even though more people are aware of "crackers" in the technological field, only few anticipate them to target human behavior (Lafrance 2004).

PSYCHOLOGICAL BACKGROUND: WHY SOCIAL ENGINEERING WORKS

Social engineering exploits human vulnerabilities, such as ignorance or naiveté, and makes use of concepts such as authority, strong emotion, overloading, reciprocation, or deceptive relationships. Most attacks can be traced back to one of the six "weapons of influence" (reciprocity, commitment and consistency, social proof, linking, authority, and scarcity) that are used to motivate people (Cialdini 1993).

Positive values such as integrity and consistency or natural behavior such as curiosity and an individual's desire to be liked and helpful can be used against target persons to gain information (Arthurs 2001; Gragg 2003; Gulati 2003). It is a part of human nature that people usually trust easily and get satisfaction out of helping those in need (Dolan 2004).

Understanding the social and psychological background of social engineering is of utter importance to be able to develop a defense strategy. Because social engineering targets people rather than technology, technological countermeasures may be of only limited use, as outlined in a separate section below on "Password Problems," which may bring more problems than they can solve.

This section focuses on peculiarities of human behavior that can be exploited in order to gain information the target usually would not give away. These soft facts stand in contrast to technical knowledge that may be used for information gathering. The following subsections show some of the psychological concepts that make social engineering work.

Strong Emotion

Strong emotion is just a collective term for the reaction to a multitude of factors that may raise people to a heightened emotional state and thus make them more vulnerable to social-engineering attacks, as they will pay less attention to the "facts" or arguments presented. Strong emotion may be invoked by factors such as:

- *Anticipation*, such as the prospect of money or a substantial prize, makes people less suspicious. But it does not necessarily need a lot of cash. An example for a social-engineering attack abusing the trigger of anticipation is discussed in the section below on "Password Problems," where a survey is discussed that shows that people will reveal their passwords for a bar of chocolate or a cheap pen.

Another example is "advanced fee fraud" mail scams. They involve requests for "up-front" money to secure your involvement in their transaction and promise great wealth in exchange. Nigeria gained notoriety in

this area, the scheme is also known as "419," named after the relevant section of Nigerian penal code. The U.S. Secret Service even runs a Web site¹ targeting this special kind of fraud.

- *Stress*: Employees may be made to think that the decisions they have to make involve serious consequences. This leads to a high level of stress in the target that in turn, lowers the chance to notice false statements made by the attacker.
- *Other triggers, such as surprise, anger, fear, excitement, and panic*, that also lead to a heightened emotional state and thus make the target more vulnerable to a social-engineering attack.

The social engineer triggers strong emotion, which serves to interfere with the victim's ability to analyze and think closely, thereby aiding the attacker to persuade the victim and to reach the desired goal (Gragg 2003; Rusch 1999).

Overloading

Human beings can process only a limited amount of information at any given time. Even though the threshold may differ significantly among different persons it is only a matter of time and volume of data that has to be processed until an overload occurs.

The strategy of overloading works by simply providing more information to target persons than they can process in a timely manner. The rationale of this attack is that wrong statements are far less likely to be spotted when included with true ones. Another form of overloading can be stimulated through elements of surprise, such as bringing up arguments from an unexpected perspective. The target is not prepared for this new point of view and therefore needs time to think it through. Social engineers make sure this time is not available by continuing their strategy, thus reducing the target's ability to process or to analyze the received information. As a result, the target is more willing to accept opinions without questioning them (Gragg 2003).

Reciprocation

Reciprocation is most easily described as an automatic urge to respond to a gift or favor one receives. Individuals are far more likely to comply with a request if they have received something of value beforehand. This could be money (from a small present to full-blown bribery) or even immaterial presents such as information, advice, or assistance. Most notably, the sheer promise of a present can lead us to reciprocate (Gragg 2003).

Individuals may feel an urge to reciprocate if given or promised something. They may want to return the favor and often even want to "exceed" the original one. This also holds true for cases when the favor someone offers was not requested. Still, the person who is offered the favor may feel a strong obligation to comply with the favor the original person asks for in return. It is of capital importance to note that the returned favor may even be more costly than the original one (Rusch 1999). Moreover, this also holds true for intimate self-disclosure. If people first

¹ U.S. Secret Service, Web site about 419 "advance fee fraud": <http://www.dced.state.ak.us/bsc/pub/publicawareness.pdf>.

become recipients of such disclosures—whether true or not—they feel obligated to respond with a personal disclosure of equal intimacy (Nass and Moon 2000).

Reciprocation can also be used in another way. Behavioral experiments show that when two people disagree, if one will yield on some point, the other will feel compelled to yield as well, no matter how small the compromise is. This is what makes a compromise possible. A cracker can exploit this behavior by making additional requests and then by drawing them back. As a result, the target may feel pressure to accede to the original request (Gragg 2003).

An example for social engineering through reciprocation is given by Mitnick. He states that members of the Hare Krishna substantially increased the donations received by first giving people a book or flower as a gift without taking it back (“It is our gift to you”) (Mitnick and Simon 2003).

The whole social system builds on the concept of giving and taking—and giving more the more one gets. That is what makes human beings so vulnerable to this kind of social-engineering attack. Thinking about the strange nature of reciprocation, “Do unto others as you would have others do unto you” is a saying, that inevitably crosses one’s mind as well.

The concept of “tit-for-tat” is also an accepted (and often the best) strategy in games theory: some even call it “the only one Evolutionary Stable Strategy generated by cooperation within and between species.”²

The best defense against the exploitation of the tendency of reciprocation is to be aware of reciprocation as a social engineering scheme. As Mitnick states:

If a stranger does you a favor, then asks you for a favor, don’t reciprocate without thinking carefully about what he’s asking for. (Mitnick and Simon 2003)

Deceptive Relationships

The longer a relationship is established, the more trust the involved persons will express toward each other. If the goal seems worth it, social engineers may invest a lot of time and passion to reach it. Mitnick, for example, describes a “two-year hack” (Mitnick and Simon 2005). Thus, attackers may take the time to build and maintain a relationship with a target with the purpose of exploiting the other person.

Ways of building deceptive relationships may be information sharing or discussing a common enemy. Mitnick even describes a plot in which he makes friends via e-mail under a false name with an employee who has already become suspicious about him. Mitnick was sharing information and technology with the employee without asking for anything in return. One key element in bonding the relationship was talking negatively about “Kevin Mitnick” without the employee realizing that actually his

pen pal was Mitnick himself. Mitnick was able to successfully exploit the established relationship by obtaining all kinds of information, essentially by simply badmouthing himself (Gragg 2003).

The concepts of liking and similarity can be abused to build deceptive relationships as well. It is a normal feature of human behavior to favor persons who have things in common with oneself. Examples are common places of birth, tastes in sports, music, art, and so on (Rusch 1999). Thus, one may trust that person even without legitimate motivation (Gragg 2003).

Authority

Another concept that can be exploited for social engineering purposes is authority. One’s daily living and business in particular build on the notion of authority. People are far more likely to perform a certain action if the person asking them to do so is presumed to be in a position of authority (Gragg 2003; Rusch 1999).

The Milgram experiment is a famous study on the obedience to authority. It was conducted by Stanley Milgram, a psychologist at Yale University. The study was published in the *Journal of Abnormal and Social Psychology* in 1963. The setup was as follows: A participant was asked to take place in a learning experiment. Failure should be punished by applying electric shocks of increasing power. The victim was actually an accomplice of the experimenter and was not really exposed to electric shocks. The participant and the accomplice drew slips of paper from a hat to determine who would be the teacher and who would be the learner in the experiment. The drawing was manipulated so that the participant was always the teacher and the accomplice always the learner. During the experiment, the participant and the accomplice could not see each other as they were placed in different rooms. Whenever the accomplice gave a wrong answer to one of the questions the participant had read, the participant had to apply an electric shock on the victim. The voltage increased during the course of the experiment. There were thirty lever switches, labeled from 15 to 450 volts. They were also labeled in clear words in groups of four. After the group labeled “Danger: Severe Shock” the last two steps only carried a label of “XXX.” When the voltage reached 300 volts, the accomplice would pound on the wall, which would be repeated at 315 volts. From this stage on, the learner would not react anymore at all. He would not answer the teacher’s questions either. The experimenter would urge the participant to continue reading questions and applying shocks, though. He would, for example, assure the participant that the shocks would not cause “permanent tissue damage.” The goal of the experiment was to find out how many of the participants would apply the highest amount of voltage to the learner, with the experimenter acting as source of authority. The outcome of the experiment was unsuspected: 65% (26 of 40) of experimental participants applied the final 450-volt shock, though many expressed being uncomfortable in doing so (Milgram 1963). The findings have been confirmed by other researchers around the world and are not tied to a specific time or location (Blass 1999). The fact that people respond so well to the concept of authority

² Tit-for-tat, the “Only Evolutionary Stable Strategy,” which may be seen as a reason why social engineering through reciprocation is successful: www.abc.net.au/science/slab/tittat/story.htm.

that they even do things they have initially disapproved of can be abused by a social engineer.

This also holds true for situations in which the person claiming to be in a position of authority is not physically present, as a study of three Midwestern hospitals shows (Rusch 1999). In the study, twenty-two nurses' stations were contacted by a researcher who identified himself untruthfully as a hospital physician. He asked the answering nurse to give a high dose of a prescription drug to a particular patient. The alarming result was that 95% of the nurses proceeded to carry out his instructions despite at least four factors should have kept them from doing so:

1. The order came from a doctor they had never met or even heard from.
2. It was communicated via telephone and not face-to-face, which is a clear violation of the hospital policy.
3. The drug concerned was not authorized for use on the wards.
4. The dosage indicated was much too high; almost double the usual daily dosage.

The fact that people react so well to the concept of authority—even when the person stating to be in a position of authority is not physically present—emphasizes the importance of policies and guidelines. The implementation of guidelines should go along with repetitive training of strict adherence, as discussed in a later section.

Integrity and Consistency

People have a tendency to believe others are articulating their true attitudes when they make a written statement unless there is strong evidence to the contrary. Furthermore, if the receiver of such a statement responds by writing a statement of one's own, it makes the writer believe in what one has written as well. This results in a feeling that both parties have expressed their true beliefs (Rusch 1999). Social-engineering attacks by means of written statements rely on this concept.

Another aspect of integrity and consistency is that people have an inclination to go through with commitments in the workplace even though they may have been wrong in the first place. People will even carry out commitments they believe were made by fellow employees (Gragg 2003).

This is the reason why automatic out-of-office e-mail replies may not be a good idea; it also highlights why "innocuous information" such as vacation schedules can be abused as well and should thus be treated confidentially, too. By acquiring sensitive information like this, a social engineer knows which employees are currently away from work. In the next step, the attacker may impersonate the affected employees and ask their fellow employees to carry out commitments. They may comply because they assume the requests come from their original colleagues.

Social Proof

Instead of developing an opinion all by themselves, people usually rely to a certain degree on what other people are doing or saying. Even actions against one's

self-interest may be taken if others do so as well without taking the time to properly think about them. Examples of this concept's power are cults from the Jonestown Temple to Heaven's Gate (Rusch 1999), though peer pressure might only be a component in these cases. The concept of social proof is also closely linked to the one of integrity and consistency mentioned above.

Mitnick instead uses the term *social validation*, which highlights one's acceptance of the action of others as validation that the behavior in question is the correct action (Mitnick and Simon 2003).

Lack of Reporting Due to Fear or Disinterest

Last but not least, one important, indirect cause of successful social engineering attacks is the lack of reporting of recognized or suspected attacks. An experiment among university students showed that they made little serious attempt to report incidents—some e-mails were even directed to the perpetrator himself (Greening 1996). These findings may stem from psychological concepts such as fear of punishment or exposure or plain disinterest.

TECHNIQUES

The following section provides an overview of some popular social engineering techniques. It is not an exhaustive enumeration of all existing methods; rather it is a selection of important ones.

Social-engineering techniques can be subdivided in several ways. An accepted approach of categorization is the subdivision into the two main categories of human-based attacks and computer-based attacks. This chapter does not follow this argument, as a successful attack often comprises multiple ingredients, some of them human-based and others with a technological background.

The following sections deal with some characteristic forms of social engineering.

Gathering Information with Google

An important step in the course of a social-engineering attack is gathering as much information as possible that can then be exploited in order to influence the target person or company. Gathering information is an area in which technical skills may come more into play than during the interaction with targets themselves. This section deals with Google³ as an example of a search engine and the multitude of information it makes available to the experienced researcher.

The Internet

It is amazing how much information is available through open sources, most notably, the Internet. Just using one's favorite search engine, one can do a detailed survey on a target's interests, relations, habits, political orientation, and a lot of other potentially interesting facts—all this while conveniently sitting on one's sofa. Google, as the market leader, is the prime example and will therefore

³ Google, world's most used Internet search engine: www.google.com.

be addressed specifically. It makes enormous amounts of private information about people available to everybody with an Internet connection with no questions asked. Thus, Google can be used as a mighty tool to pry into people's private lives, as more and more information becomes available online.

In 2005, Elinor Mills of CNET⁴ (News.com⁵) showed exactly this when she researched and published personal information about Google CEO Eric Schmidt, including his salary, his hobby as an amateur pilot, his neighborhood, and his political donations (Mills 2005). Understandably, Google was not amused, and reacted with an interview ban on CNET reporters (as reported by CNET themselves), thereby essentially blackballing CNET (Westhoven 2005).

If used correctly, Google can be a powerful tool for gathering information relevant to social engineering. Sources to learn advanced search techniques are available for everybody—for example, the excellent *Google Hacks* (Calishain and Dornfest 2004). But Google can also be (ab)used as a tool for penetration testers (Long, Skoudis, and van Eijkelenborg 2004)—and thus as an attack tool for social engineers.

In the past few years, numerous news stories have been published about using Google to gain otherwise private information—for example, credit card data.⁶ This could be accomplished through a simple trick, namely using a special operator Google provides for searching ranges of numbers. For example, “year numrange:1990–2000” will find instances of “year 1990” to “year 2000,” a shortcut for the above shown numrange example is “year 1990..2000”. Using the numrange operator, a multitude of valid credit card numbers was available online. This possibility may, of course, have existed before Google.

Another story in the popular press pointed out the danger of known URLs Web cams use by default.⁷ Certain Web cam models use predefined URLs to make the images they record available online. If no precautions are taken and such a URL is accessible publicly from the Internet, Google's robot will assimilate the information when it scans the site. Thus, by searching for parts of the known default URL used by Web cams, publicly-accessible ones can easily be found. Who needs blast-proof walls, bullet-proof windows, and high-security authentication if everybody around the world can peek over your shoulder with the click of a button?

Newsgroups

The Usenet is an Internet-based bulletin board system that allows reading and posting of “news” in different “newsgroups.” It is one of the largest and oldest cooperative networks, and it is still in heavy use today.

Google maintains archives of posts to newsgroups dating back to 1981. Knowing a target's e-mail address, the search engine can be used to gather information about a person's or company's interests. An example might be relations to other people, information about hobbies or even unlawful behavior; e.g. asking for a “crack” to an application in an adequate newsgroup.

But it does not stop there. Finding a Usenet post by a certain person via Google groups provides potential attackers with information about the IP address of the computer the post was issued from via the header field “NNTP-Posting-Host” and thereby:

- The target's Internet provider (type “nslookup IP” in a command shell).
- The geographical location the post originated from by tracing the route (“tracert” on Windows computers; may also be used as an alternative to “nslookup” on Windows 9x systems).
- The newsreader client the target is using can easily be found investigating the “X-Newsreader” header field of the post.
- Using the information about the newsreader, the operating system of a target can be guessed.

All of the above information may be fake, but most of the time, people either do not know or do not care about the risks arising from tracks they leave while surfing the Web or posting to newsgroups. In fact, a lot of people even consider it a good practice to use their real names in Usenet postings, which opens a point of attack for social engineers.

On the other hand, it is a justified argument that most of the Usenet information is very old in many cases. Considering the age of posts Google may return (back to 1981), it is likely that users may have changed addresses.

Phone Listings

The World Wide Web and Usenet are not the only sources of information Google provides. The “phonebook” operator searches both business and residential phone listings. Using the “rphonebook” and “bphonebook” operators, only residential and business, respectively, listings are searched. Phone listings other than those provided by Google may be used as well, of course.

If a social engineer knows the city a target lives in, phone listings provide a great opportunity to reveal not only the phone number but also, and more important, the target's address.

Google Maps

Using Google's free online map service Google Maps, a social engineer is able to map acquired address information to visual information about the target's surroundings. Given the target's home and working address, an attacker can even use the service to calculate a route between the two. Google Maps is able to show satellite data of a region that can be of great use for a social engineer who is not familiar with the place. The satellite pictures vary in age and detail but can be taken as a good first guess, though.

Social and Business Networking Sites

The growing popularity of MySpace.com⁸ and other social networking sites is an acceptable gift to any potential attacker. MySpace.com hit the mark of 100 million accounts on August 9, 2006. On MySpace.com, users can create a profile for free in which they describe themselves. The data is searchable and can provide a wealth of information about a person or organization that can be abused by a social engineer. People reveal all sorts of personal information, such as age (sometimes birth dates), gender, location, marital status, education, sexual and political orientation, family/relatives, and preferences regarding books, music, movies, television, and so on. In addition, users can add other users to their “Friend Space,” thus revealing interpersonal relationships. There is also the opportunity to add pictures and videos. With a bit of luck, a social engineer can extract valuable information about people and organizations that can be abused in ensuing attacks.

The fact that sites like MySpace “work” is confirmed by news stories that even police use the service successfully to solve criminal cases—for example, a triple homicide case⁹ and the case of probation violation by a sexual offender.¹⁰

According to MySpace.com, the service is also used by businesspeople and coworkers interested in networking. Other providers, like openBC,¹¹ specialize in business networking. User profiles of business networking sites may provide information on current and previous companies, job title, language abilities, affiliated organizations, detail on education, earned degrees and certifications and, most important, contacts.

ZoomInfo¹² is another service that can provide valuable information about people and companies to an attacker. In contrast to the aforementioned solutions, ZoomInfo consists not only of a passive part (“BeFound”), where people can add their own profiles, but it actively searches and parses information from a wealth of sources, “such as Web sites, press releases, electronic news services and SEC filings.” The service thus describes itself as “the premier summarization search engine” and promises comprehensive information on over 32 million business professionals and 2 million companies (September 2006). Information on people is often complete with portrait and details such as employment history, education, board membership and affiliations, and more. Information on companies contains key data such as address, telephone numbers, revenues, industry, and number of employees but also records on key people such CEOs, Chairpersons, and people with other important posts. ZoomInfo also provides links to Web references that usually contain more data. An upgrade from the free service to “BeFound Pro”

enables even more sophisticated search opportunities—for example, all registered employees of a certain company can be listed, which may be a great source of information for an attacker who wants to conduct an impersonation attack. In a test conducted by us, ZoomInfo yielded information not only on U.S. but also (bigger) European and Asian companies.

In the past, an attacker may have had to steal an organizational chart to gain insight into a company’s structure. However, nowadays a visit to Web sites such as openBC and ZoomInfo can suffice.

Social networking is a characteristic trait of humankind and has thus always been a “risk” when considered from a social engineering point of view. However, there are special risks attached to online social networks:

- Everyone can participate easily and within a short timeframe, no matter where one is located.
- Information on networks by different people may be combined. Information gathered through online social networks can be compared to the “traditional way” of stealing someone’s address book—the combination of information from online networks of different people is equivalent to stealing the address books of all affected participants.
- Online social networks “are both vaster and have more weaker ties, on average, than offline social networks” (Gross, Acquisti, and Heinz 2005). People grant access to their online networks to rather unknown people.

On openBC, for example, there are users with several thousand confirmed direct (first-level) contacts. One may receive a “may i join?” message by such individuals minutes after registering and many users seem to comply, otherwise such “harvesters” would not have so many contacts. One should think twice before adding such users to one’s “friends.” Many online social networks allow for “privacy” settings according to different levels of information protection—for example, information may be:

- world-readable
- readable only by friends and oneself
- private: readable only by oneself.

Allowing foreign individuals access to the “inner circle” of friends is thus a potential security leak when the security level is set to level 2 (readable only by friends). Even worse, few users make use of limiting privacy preferences at all (Gross et al. 2005).

Weblogs, Blogs

Weblogs, which are usually called “blogs,” are sites where individuals publish information such as news or comments on recent events. In the past few years there has been a steep rise in the use of blogs. Blogging can evidently lead to the same revelation of personal information as participating in online networking sites, with the exception that blogs usually are publicly accessible by design, providing not even the possibility of privacy preferences. Blogs and all their variations—like photoblogs and moblogs (blogs composed using mobile devices like

PDAs)—may describe someone's life and social network (Nolan and Levesque 2005).

Internet Relay Chat and Instant Messaging

Other possible information sources are Internet relay chat (IRC) and instant messaging (IM) solutions. Both may disclose the IP of potential victims, for example. Tracking when a certain individual is "online" can be used to generate timetables of people's behavior. Information about when a certain employee is out of the office or at home may be used in impersonation attacks.

Companies' employees may gather in certain IRC channels, so that knowledge of one employee's nickname can lead to the discovery of other employees and their information. The channels an individual joins may indicate personal preferences. The private information and social network of a person may be uncovered.

Instant messaging solutions usually allow the creation of profiles, in which users can enter similar private information for those on online social networks, thus carrying the same risk.

But IRC and IM solutions can also be abused actively, as described in a CERT Incident Note; attackers may trick users into downloading and executing malicious software, for example (CERT 2002).

Spying and Eavesdropping

Spying and eavesdropping constitute an important source for social engineers in gathering information, either to find out what they are after directly or to gain more knowledge about a situation, environment, or victim in order to have a firmer basis for a pending attack.

The following discussion provides a brief overview of different technological and nontechnological approaches to spying and eavesdropping. Some of them are more obvious, some less:

"Shoulder surfing" denotes the easiest form of spying. It refers to using direct observation techniques in order to obtain the information sought. Therefore, it is particularly effective in crowded places, where it is easy to stay unnoticed when looking over someone's shoulder. A typical application for shoulder surfing attacks is when victims enter their pin code at an ATM and the attacker looks closely to remember the password. But it can also be done at a distance—using binoculars, for example—thus reducing the chance of getting caught or looking suspicious.

Shoulder surfing is an easy-to-conduct attack with a low risk attached to it. Countermeasures are as simple as they are effective: prying eyes are best fended off by simply shielding the confidential information from view—for example, by placing yourself between a camera and the information to protect or cupping your hand to hide your pin code while entering it using a keypad.

A study on shoulder surfing risks concerning graphical passwords (in this case, photos of faces have been used) shows differences in the vulnerability of the approach to shoulder surfing, compared to alphanumeric passwords. Graphical passwords that were entered via keyboard were significantly more difficult to spy on than those entered via mouse and both nondictionary and dictionary passwords (Tari, Ozok, and Holden 2006).

A more modern form of spying can be accomplished through technology such as miniature cameras, which can be hidden easily. Nowadays, tiny wireless spy cams are available online to everybody for as little as \$50, complete with the option to record sound. Another kind of attack has already been mentioned, namely using an Internet search engine to find typical URLs of publicly available Web cams that have been placed by security-unaware people.

Using a "key logger," passwords can easily be spied on. They can be implemented as applications (software), which record the sequence of characters entered through the keyboard or as small devices (hardware), which are placed between the keyboard jack and the actual connector and store the keystrokes on internal memory.

Each of the approaches exhibits specific pros and cons. Software key loggers can be installed via malicious email attachments, for example, without the attacker needing to be physically present. Logs can be sent back via e-mail as well. On the other hand, they may easily be detected by security-aware users or antivirus scanners. Instead, hardware key loggers are absolutely invisible to software running on a computer and can therefore not be detected by antivirus scanners. But as they are hardware devices, they have to be planted in the first place and collected later for analysis, which makes access to the monitored system mandatory and thus poses a greater risk of discovery and punishment, if trespassing is involved.

A lot of different types of key-logging applications are available and they can be augmented with screen-capturing functions, instant messenger logging, etc. A famous representative is Spector¹³, which has, for example, been mentioned in the news as a tool to catch cheating spouses.¹⁴ The same holds true for hardware key loggers, which are available for different interfaces. KeyGhost¹⁵ key-logger devices are available for PS2 and USB interfaces, for example.

Using a "sniffer" application, passwords and other confidential information can be extracted from the network environment. Access to the network is mandatory but can be gained through different measures—for example, by installing hidden software on a local PC or by hiding a "listening box" at the target site.

Ethereal¹⁶ (and its successor, Wireshark¹⁷) is a free "protocol analyzer" that provides all the conveniences one can ask for of a good sniffer. It can capture data from many different interfaces, dissect more than 700 protocols, and read capture files by other popular sniffers. Filters can be set and output can be saved in different formats. Last but not least, it optionally makes available a nice graphical user interface (GUI).

¹⁶ Ethereal, a free "protocol analyzer," the best-known free network sniffer: www.ethereal.com.

¹⁷ Wireshark, successor to Ethereal, a free "protocol analyzer": www.wireshark.org.

Dsniff¹⁸ takes the convenience one step further. It is a collection of tools for network auditing and penetration testing, which consists of several applications.

dsniff, filesnarf, mailsnarf, msgsnarf, urlsnarf, and webspay passively monitor a network for interesting data (passwords, e-mail, files, etc.). arp-spoof, dnsspoof, and macof facilitate the interception of network traffic normally unavailable to an attacker (e.g., due to layer-2 switching). ssh-mitm and webmitm implement active monkey-in-the-middle attacks against redirected SSH and HTTPS sessions by exploiting weak bindings in ad-hoc PKI. (from the dsniff homepage)

Insufficiently secured wireless networks make sniffing even easier, as all an intruder needs is the right kind of equipment and to be within range of a wireless transmission. The signal can be picked up from outside the building, driving, or walking by. “Wardriving” and “warwalking,” respectively, are coined from the term “wardialling” which refers to phoning lots of numbers in order to find out which ones did not answer with a dial but rather a data tone. If a target is not using wireless networking, an attacker can also gain access and plant a rogue wireless access point. Once installed, the intruder can attack safely from outside the building. The chance of discovery is low and even then, the wireless access point may be mistaken for a regular piece of hardware (Robinson 2002).

Telephone

Some kinds of social-engineering attacks are easier to pull off in person or via the telephone. The concept of overloading is much easier to apply and is far more likely to work when engaging someone in an oral debate than through an exchange of written e-mails, simply because the amount of information per time interval is higher in direct conversations. In addition, spoken words must be processed the instant they are received, whereas written messages can easily be skipped back on, in case something was not clearly understood. Even a live text chat does not provide the same level of interaction and information richness (and therefore, the potential of overloading) a personal conversation does.

One of hacker “Bernz’s Social Engineering Tips” is:

Try to be a woman: It’s proven that women are more trusted over the phone. Use that to an advantage. Get a woman’s help if needed. It’s even better if you’re actually a woman (a rarity in our biz). (Bernz 1995, Bernz’s social engineering tips)

In another article, he even recommends voice changers in order to sound like a woman when on the phone. Because most people in the computer business are still men, posing as a woman can help a male social engineer reach his goal. “Sound helpless, they love it. (...) If you pretend

to be a woman, they’ll give you plenty of leeway” (Bernz 1995, The complete social engineering faq).

It is easy to pose as a woman in nonverbal conversation—for example via e-mail; however, it is difficult to make people believe you really are a woman, if you are not. Contrarily, it is easy to “prove” that you are a woman when on the phone (with the right voice) and harder to pose as one, if you are not.

Face-to-Face

A social engineer who is a master of the trade succeeds at face-to-face social engineering. It requires both nerves of steel and a quick mind in order to always have an answer ready, especially to unpleasant questions. Imagine lying to people’s faces without showing the slightest hint of nervousness or scruples, against the background of the permanent danger of being caught, in person, on the spot. This may seem difficult to most people, but unfortunately there are many who are great at this.

Face-to-face social engineering usually goes along with impersonation. The attacker may pose as a fellow employee, a repairperson, a superior from a distant subsidiary, information technology (IT) support personnel, or another trusted third party, such as the vice president’s secretary (Arthurs 2001).

A common technique is the forgery of badges. These are quickly printed, and with today’s technology it is hard to tell the difference between an original and a fake if they are not secured in other ways (e.g., by incorporating a transponder chip).

Successful social engineers have a significant advantage; they usually have very attractive personalities. They are characteristically fast on their feet and quite eloquent (Mitnick and Simon 2003). Part of such charisma is inherent, part can be learned.

Dumpster Diving

“Dumpster diving” is a method used by intelligence agents and investigators all over the world. It is nothing more than the act of taking trash from dumpsters of an organization or individual in the hope of acquiring information. Dumpsters outside buildings are ideal targets, as they are usually far less secured than inside ones and no legal implications exist.

Depending on the amount, the trash is usually collected from the dumpster and taken off site for investigation. That way, the act of dumpster diving itself can be limited to screening the trash for promising findings, which makes the process far less time consuming. At a later stage, information may be recovered by applying thorough analysis.

Why would trash have value to anybody? It is amazing what one can learn about target persons/companies by sifting through their waste. People mindlessly throw away all kinds of materials, including but not limited to:

- bills
- financial statements
- credit card statements
- old checks

¹⁸ Dsniff, a collection of tools for network auditing and testing: www.monkey.org/~dugsong/dsniff.

- medical prescription bottles
- work-related materials, such as memos, meeting agendas, and letters revealing names, telephone numbers, and other information (Lively 2003, Mitnick and Simon 2003)

Take a second and think about what social engineers might find in your trash even if they picked it up only for a short time. Many details, which may seem unimportant to insiders, can be valuable information to a social engineer. Organizational charts, for example, are a great source of information for a social-engineering attack as they reveal hierarchies of authority throughout the organization.

What is worse, and what makes dumpster diving an interesting form of acquiring knowledge about target persons or companies, is the low risk associated with it. It is not forbidden to search through someone else's trash, as long as one is not trespassing or violating the law in other ways. As the Defense Security Service's *Employee's Guide to Security Responsibilities* puts it, dumpster diving is perfectly legal in the United States:

Stealing trash is not illegal. The Supreme Court ruled in 1988 that once an item is left for trash pickup, there is no expectation of privacy or continued ownership. (Defense Security Service 2002)

Local cities and counties may have specific laws that forbid dumpster diving, though. Circumventing a lock, trespassing, and leaving a mess are illegal.

A well-established countermeasure to dumpster diving is the practice of using shredders on classified documents before throwing them away. However, there are different ways shredders are built. Older and cheaper shredders cut documents only in one direction, resulting in spaghetti-like snippets. With enough time on hand (respectively, with the prospect of a positive cost-benefit equation) they can be reassembled quite easily. Crosscut shredders cut paper in two directions, vertically and horizontally. Still, this is no statement of quality on its own, as the residue may be of arbitrary size. This is why the *National Industrial Security Program Operating Manual* of the Department of Defense (DOD) demands a strict maximum size for the residue:

Crosscut shredders shall be designed to produce residue particle size not exceeding 1/32 inch in width (with a 1/64 inch tolerance by 1/2 inch in length). (U.S. Department of Defense 1997, paragraph 5-705 "Methods of Destruction")

In the United States there are several federal regulations governing the proper disposal of personally identifiable information—for example, the Family Educational Rights and Privacy Act of 1974 (FERPA),¹⁹ the Health Insurance Portability and Accountability Act of 1996 (HIPAA),²⁰ and

the Gramm-Leach-Bliley Act of 1999 (GLBA).²¹ FERPA covers the privacy of education and some medical records; HIPAA covers the privacy of personal health information; and GLBA covers the security of financial information.

Phishing

Phishing is most easily described as the practice of directing users to fraudulent Web sites. It is a problem despite all efforts to fight it as it is estimated that some phishing attacks have persuaded up to 5% of their audience to provide sensitive information to spoof Web sites (Dhamija, Tygar, and Hearst 2006).

Big names like AOL²², eBay²³, PayPal²⁴ and a large number of financial institutions have been and still are targets for phishing attacks.

A social engineer phishing for passwords to bank accounts, for example, may imitate an e-mail by the victims' bank and ask them to log in as quickly as possible—for example, because of a fictitious "emergency." The e-mail mimics the looks of "real" e-mail by the financial institution—for example, by using the same colors and logos. The attacker provides a link to the "bank's Web site" inside the e-mail. However, the link only seems to point to the bank's Web site, while in truth it leads to a Web site controlled by the social engineer. As soon as the victims try to log on using their credentials, they actually send the confidential data to the attacker, who now has reached the goal of stealing the password. To perfect the masquerading process, the attacker may now output an error message "sorry, wrong password" and then redirect the victims to the real original Web site with which they believed they were interacting. This way, the victims are less likely to discover the scam and may think they just accidentally typed their password wrong the first time. As a result, they will not be alarmed and change their password, which gives the attacker more time to abuse the acquired information.

For example, phishing could be conducted by exploiting bugs or security holes in browsers and e-mail clients, most notably but not limited to Microsoft's Internet Explorer and Outlook and Outlook Express, as they are most commonly used today. Legitimate techniques such as JavaScript may be used in a malicious way. Because phishing relies on masquerading techniques, bugs that can be abused to cover the tracks of leading to Web site address other than the one of the real organization are popular among the phishing community. HTML e-mails (as opposed to plaintext e-mails) are a good example. If an e-mail is sent as HTML rather than plaintext, a link may show a different text than the address it is actually pointing to by using the "<A>" tag. This way, a link showing the text "www.myrealbank.com" may actually lead to the Web site "www.thefalsebank.com" when clicked on.

²¹ Gramm-Leach-Bliley Act of 1999 (GLBA): www.ftc.gov/privacy/privacyinitiatives/glbact.html.

²² America Online (AOL), a well-known Internet service provider (ISP): www.aol.com.

²³ Ebay, a big Internet auction platform: www.ebay.com.

²⁴ Paypal, a simple way of sending and receiving payments online: <https://www.paypal.com>.

¹⁹ Family Educational Rights and Privacy Act (FERPA): www.ed.gov/offices/OIE/fpc/ferpa.

²⁰ Health Insurance Portability and Accountability Act of 1996 (HIPAA): www.hhs.gov/ocr/hipaa.

Usually, hovering above the link will show the real destination in the status bar. A trick to spoof this occurrence as well may be of great use to attackers trying to deceive people. After clicking the link, a browser window may pop up and surf to the indicated address, thereby disclosing the false nature of the link. Again, a bug that allows hiding of the genuine events could be abused to cover the tracks of the attacker.

One early trick involved use of the “@” sign: a URL such as “www.thegoodurl.com@thebadurl.com” may trick people into believing they are visiting thegoodurl.com when actually everything before the “@” is just understood as a username by the Web server. If user “www.thegoodurl.com” does not exist, however, the page (“thebadurl.com”) will load just as well. Fortunately, this potential security hole no longer works for most new browsers. The following list provides an overview of browser-specific behavior:

- The following browsers issue a security warning and asked the user if they should proceed:
 - Internet Explorer 6.x
 - Opera 8.x
 - Firefox 1.x
 - Netscape 8.x
- The following browser proceeds without asking:
 - Safari 2.0.3 on Apple

Currently, there are efforts to develop antiphishing techniques, in which one solution may be to detect phishing attacks by using fake responses that mimic real users (Chandrasekaran, Chinchani, and Upadhyaya 2006).

New or Creative Methods

Considering surprise and curiosity as two important concepts for successful social engineering attacks to rely on, the development of creative or new methods is a great opportunity for potential attackers. In June 2006, for example, a story on “Social Engineering, the USB Way” hit the news.²⁵ A security professional who had been hired for a security assessment described a new method to compromise companies’ networks; it works by scattering specially prepared USB drives in the parking lot, smoking areas, and other areas frequented by employees. Nested between a set of assorted pictures, a Trojan was hidden on the drive. The idea was that curious employees who “found” the seeded devices would eventually plug them into their computers inside the company’s network to watch the planted images, accidentally launching the Trojan that would phone home to the attacker. Fifteen of the twenty USB drives were found, and all of the found devices were plugged into employees’ computers. Thus, the idea turned out to be a big success that also came along with other benefits for potential attackers: Apart from seeding the USB drives, which can be conducted in

a rather unobtrusive way (e.g. at 6 A.M., as the author of the original article describes) social engineers do not even have to go near the company’s building but can instead enjoy information sent out directly to their headquarters.

Another surprisingly easy way to conduct a social-engineering attack is to let go of most cover-up efforts and just ask users for their usernames and passwords, as described in the section on “Password Problems,” below.

Reverse Social Engineering

Reverse social engineering (RSE) is an even more advanced form of social engineering. In contrast to traditional social engineering, in reverse social engineering, the cracker is thought to be on a higher level (e.g., a superior or administrator) than the legitimate user (Allen 2001). An example of RSE is when crackers cause a problem on the target’s network or computer and then make themselves available to fix the problem. The trust they earn by helping the target can then be abused to obtain the information they are after (Gragg 2003). But the problem does not even have to be real; it may be sufficient to just make the victim think there is a problem (Mitnick and Simon 2003).

If the victim is the one acting and the actual attacker only reacts to a cry for help, the victim is a lot less likely to be suspicious. As Mitnick states:

The attacker just sits and waits for the phone to ring, a tactic fondly known in the trade as reverse social engineering. An attacker who can make the target call him gains instant credibility: If I place a call to someone I think is on the help desk, I’m not going to start asking him to prove his identity. That’s when the attacker has it made. (Mitnick and Simon 2003)

The victim asks the attacker for help, which the social engineer is able to provide easily, as the attacker has caused the incident. This leads the victim to trust the attacker, which is, in fact, nothing more than the acceptance of authority, which in this case (apparently) was confirmed by the demonstration of expertise.

PASSWORD PROBLEMS

A lot of social-engineering attacks try to steal passwords. This fact is rather unsurprising, as passwords are still the most commonly used authentication mechanism (Tari et al. 2006).

This section shows problems passwords entail and why they are partially inherent to the system.

The information presented stems from a survey²⁶ undertaken by the organizers of Infosecurity Europe²⁷ 2004 to find out more about the security consciousness of workers concerning company information stored on computers. The survey was conducted at Liverpool Street Station in London and consisted of a series of questions

²⁵ Darkreading, a security news site. June 7, 2006. “Social Engineering, the USB Way”: http://www.darkreading.com/document.asp?doc_id=95556&WT.svl=column1_1—additional comment by the author at www.darkreading.com/boards/message.asp?msg_id=134658.

²⁶ Infosecurity Europe 2004 survey, results summarized in a mailing list thread: www.iwar.org.uk/pipermail/infocon/2004-April/001287.html.

²⁷ Homepage of Infosecurity Europe: www.infosec.co.uk.

that included the question “What is your password?” People were promised a chocolate bar for parting with their passwords (concept of anticipation). The results were quite alarming:

- A total of 37% of the 172 workers surveyed immediately gave their password when inquired about it. The number of people giving their password is alarming. It should be noted, though, that the sample size is small and it may thus be difficult to generalize the results.
- Another 34% initially refused but gave their password when being applied simple social engineering techniques on—“I bet it’s to do with your pet or child’s name.”

This shows that social engineering can be easy at times; though some respondents may have cheated and it is hard to imagine that more than two thirds of people may give out their passwords so thoughtlessly, one can conclude that a considerable number of people do not require any social engineering at all. Just asking for their password—or promising them some chocolate might suffice.

The most common password categories were

- family names such as partners or children (15%)
- football teams (11%)
- and pets (8%)

In the 2003 survey, the most common password had been “password” (12%) and the most popular category their own name (16%) followed by their football team (11%) and date of birth (8%). Respondents had been promised a cheap pen in exchange for their passwords (Leyden 2003).

These might be worth a try for any social engineer struggling to find out the password of a given person. The results also show why people should be (made) aware about the risks of thoughtlessly giving out personal information. Even facts that seem unimportant can be of value to an attacker.

Only 53% of those surveyed said they would not give their password to someone calling from the IT department, as this could cause a security breach. This leaves more than half the workers vulnerable to one of the simplest (and thus most popular) social-engineering approach, the attacker pretending to be someone from the IT department and calling victims requesting their password in order to “solve a problem.”

Four out of 10 colleagues knew their colleagues’ passwords. This is an alarming finding as well, as many attacks originate from the inside of an organization. The *2005 CSI/FBI Computer Crime and Security Survey* states that incidents originating from outside and incidents originating from inside are roughly balanced, which is contrary to the popular belief that most attacks do originate from inside (Computer Security Institute 2006). However, the remaining share of about 50% of incidents originating from inside an organization should make people wary of telling their passwords to colleagues.

A total of 55% said they would give their password to their boss. The knowing reader immediately recognizes

the concept of authority that was already mentioned in the section about the psychological background of social engineering. More than half the survey respondents would give their password to their boss—this underlines the danger posed by impersonating attackers.

Two thirds of workers use the same password they use for access to their company information for personal access for operations such as online banking and Web site access. This result clearly originates from the difficulties people have remembering passwords. This finding calls attention to the annoying fact that attackers might get even more than they asked for. With two thirds of people using the same password for multiple purposes, a password acquired for a computer account may also be the key to other “advantages” for the social engineer.

Respondents used an average of four passwords. This result shows that the problem of simple passwords is inherent to the system. The reason people choose simple passwords that present a security threat is because they have problems memorizing them.

The following facts were gathered concerning the duration of password use:

- A total of 51% of the passwords are changed monthly.
- A total of 3% of the passwords are changed weekly.
- A total of 2% of the workers change their passwords daily.
- A total of 10% change them each quarter.
- A total of 13% change them rarely.
- A total of 20% never change their passwords.

In addition, many workers who had to change their password on a regular basis wrote it down on a piece of paper or in a word-processing document in order not to forget it. Again, people’s difficulties in remembering passwords make it simple for an attacker. With one fifth of them never changing their password, such targets represent easy victims.

The final finding to be mentioned here is the attitude toward passwords in general:

- A total of 80% of workers were fed up with using passwords.
- A total of 92% said they would prefer some sort of biometric technology to them, such as fingerprint and iris scanners, smartcards, or tokens. As pointed out later in this chapter, in Figure 3, in 2005 only 15% of the companies responding to a survey used biometrics. (Infosecurity Europe 2004)

A study conducted by researchers at Brigham Young University led to similar results—80% of the participants gave their username and 60% gave their password. An auditor gained physical access to the audited company and introduced himself as “performing a survey to assess the security of our network” (Orgill et al. 2004). One reason for the success of the mentioned audit may be the factor of surprise: The first three questions of the survey asked for name, username, and password of the participating employee. Who would suspect such a blatant

approach to gain users' passwords, especially if the attacker is already inside the building and wearing a valid badge?

The difficulties in remembering multiple complicated passwords are usually described by basic human cognitive limitations from the psychology literature. A way to mitigate these problems may be the use of graphical passwords, which leads to an increase in memorability. Another surprising finding of the study is that dictionary passwords are less vulnerable to "shoulder surfing" (e.g., observation during password entry) than nondictionary passwords. This effect may be attributed to slower keyboard entry of nondictionary passwords (Tari et al. 2006).

In addition to people choosing weak passwords, there is always the risk of password-cracking tools, which can be used to find out passwords. Considering Microsoft Windows, for example, which is still by far the most used operating system for desktop computers, a multitude of tools is available. L0phtCrack²⁸ was the first well-known password cracker for Windows passwords and has since changed its image to an "award-winning password auditing and recovery application." It allows dictionary (using a set of words to try as a password) and brute-force attacks (trying all possible combinations of a set of given characters). Precomputed hash tables can be used as well. A Project called RainbowCrack²⁹ takes this last idea one step further. Precomputed hash tables for a wide range of characters are available online for free.

Considering the above-mentioned facts, it is no surprise even Bill Gates, founder of Microsoft, thinks the days of traditional passwords are numbered:

There is no doubt that over time, people are going to rely less and less on passwords. People use the same password on different systems, they write them down and they just don't meet the challenge for anything you really want to secure. (Kotaida 2004)

The aforementioned facts show that the attempt to prevent social-engineering attacks by establishing technological countermeasures can lead to new, even more severe problems.

AN EXAMPLE: THE POSTMAN AS SENIOR PHYSICIAN

Well-trained social engineers have the potential to get almost everywhere they want. Some readers may not believe it. A trained postman posed as a doctor applying for a job in a psychiatric hospital. He got the job and worked as a senior physician for one and a half years.

He prescribed drugs, held seminars in front of hundreds of "colleagues," invented new terminology, which was accepted without any doubt, and even appeared in court—not as a suspect but as an appraiser in more than twenty cases. He was awarded a professorship at a university, which he kindly turned down. This may sound impossible but it really happened.

Gert Postel's story sounds almost unbelievable—but it is true—a trained postman working as a senior physician in a Saxon psychiatric hospital for one and a half years. How did he manage to fool so many people, including doctors and politicians? The following section is based on an interview transcript provided on his homepage.³⁰

Postel has a history of posing as a medical doctor, but this was his masterpiece, which ultimately got him four years in jail—but first things first.

The position had been advertised in medical newspapers. Postel applied normally and was picked out of thirty candidates. He had gathered a huge amount of knowledge on psychology by self-education and through two former girlfriends who had been studying medicine. This way, he managed to convince the board with a paper he had written, which was ironically discussing Thomas Mann's novel "Confessions of Felix Krull, Confidence Man," about a young man who recognizes that having a good appearance and a convincing attitude more than compensates for lack of experience or ability. With his appearance and (false) references he outwitted even experienced physicians.

Postel's acting was so convincing that he managed to keep up the masquerade for one and a half years—and he was discovered only because the parents of an assistant remembered his name from a prior coup. He remembers thinking, "Who actually is the fraud, me or them?"—for example, he introduced new terminology, terms that do not exist. In front of a hundred psychiatrists he talked about the "Bipolar Depression of the Third Degree"—a supposed psychiatric term that does not exist. No one asked a single question about it as Postel cleverly abused the concept of authority through knowledge: every one who had asked about the term would have implied their own incompetence. He used the same trick when during the job interview he was asked what his doctorate was in: he answered "Cognitive-Induced Distortions in the Stereotypical Formation of Judgment," which, he admits, "is nothing else than the stringing together of meaningless words."

Postel highlighted the importance of mastering the psychiatric jargon for making his way up to the top. By using the jargon, Postel applied three concepts of social engineering at the same time; he not only gained authority/credibility through (false) expertise but also lowered the chance of suspicion by invoking a feeling of "having something in common" and used the concept of overloading by exploiting the fact that human beings can process only a limited amount of information at any given time.

²⁹ RainbowCrack, a password cracker for Microsoft Windows (and other systems using vulnerable password hashes), which works by generating tables of precomputed passwords and then matching the encrypted passwords against these, which is much faster than trying to encrypt password guesses and then comparing them to the encrypted one: www.antsight.com/zsl/rainbowcrack.

³⁰ Homepage of Gert Postel, a trained postman successfully posing as a senior psychiatrist for one and a half years. English translation of a TV talk show: www.gert-postel.de/english.htm. Gert Postel's home page (German): www.gert-postel.de.

He also describes an exceptionally well conducted impersonating attack when remembering calling the senior consultant at the hospital as “Director of the University Clinic of Neurology in Muenster” and recommending “his assistant, Dr. Postel,” for the position. Two hours later, the consultant was talking to “Dr. Postel” and referred to the earlier telephone conversation and how full of praise it had been, which Postel saucily dismissed as exaggeration.

Another anecdote concerns the police. When Postel had finally been unmasked and decided to flee from imminent arrest, the police managed to track down his exact location in a flat. But Postel had somehow smelled a rat and therefore pinned a note to the door: “Dear Simone, I’m with Steffi in Bremen. Will be back in a week. See you, yours...” With Postel looking through the spy hole and only ten centimeters between him and the police, they decided to leave again, as “he cannot be there if he is in Bremen.” This can be seen as social engineering through surprise: the trick worked because the situation developed in such an unexpected way. No one believed a wanted criminal could act so impertinently.

But how did he manage to escape in the first place? Postel had built up a deceptive relationship with the senior consultant, who helped him to get away. Postel, looking back, says:

the senior consultant told me that I was suspected of a serious offence. I was suspended until the next day. With incredible logic I concluded that finally the cat was out of the bag and that I should terminate my stay immediately. In fact, the senior consultant acted as accomplice (Gert Postel on his homepage).

The story even has a component of reverse social engineering in it: in the beginning, the hospital was searching for a senior physician. This can metaphorically be seen as a “cry for help,” which Postel “answers” when he makes himself available after reading about the job advertisement in a medical newspaper. If you invite physicians you usually don’t expect con men, that’s another factor that made them so vulnerable to his attack.

As Mitnick states:

Manipulative people usually have very attractive personalities. They are typically fast on their feet and quite articulate (Mitnick and Simon 2003).

This holds true for Postel, as a quote³¹ in the German newspaper *Die Welt*³² by his former boss shows: “The man immediately convinced me. His appearance, his references—I thought to myself, we cannot get a better physician.”

Though Gert Postel’s story is not specifically linked to computing, it illustrates a wealth of different social engineering attacks in just one real-world example.

DEFENDING AGAINST SOCIAL ENGINEERING

Because social engineering exploits the human factor as the weakest link in an organization’s security chain, the most effective defenses rely on educating people. Nonetheless, technological approaches also have to be considered; phishing attacks, for example, might be a lot less successful if browsers and mail clients were designed in a more secure way.

A Multilayered Defensive Approach

In order to maximize abilities to prevent or detect social engineering attacks, a comprehensive approach is required. Requiring employees to sign a security policy on entry to the organization, for example, will not per se lead to an increase in security, because policies have to be reinforced and maintained. Thus, multiple layers of security should be introduced (Gragg 2003; Thornburgh 2004; Orgill et al. 2004). Gragg’s concept, *A Multi-Level Defense against Social Engineering*, consists of the following levels of security:

- *Foundational Level*: Security policy addressing social engineering
- *Parameter Level*: Security-awareness training for all users
- *Fortress Level*: Resistance training for key personnel
- *Persistence Level*: Ongoing reminders
- *Gotcha Level*: Social engineering land mines (SELM)
- *Offensive Level*: Incident response (Gragg 2003)

The importance and roles of policies and security-awareness training will be highlighted in the following sections. Key personnel, such as helpdesk operators, who are likely to be targeted by social engineers should undergo resistance training in order to prepare for specific social engineering attacks. One of the essential features that should be instilled through resistance training is that employees must realize that they are personally vulnerable to such attacks. At the Persistence Level, personnel should regularly be reminded of the possibility of social engineering attacks. Social Engineering Land Mines (SELM) that are set at the Gotcha Level should assist in the defense against social engineering attempts. Examples for SELMs are callbacks by policy or bogus questions. Finally, there should be a well-defined process that employees can initiate as soon as they suspect something is wrong (Offensive Level). Incidents should be logged, the information may be used at the Persistence Level to remind employees of the possibility of attackers conducting social engineering attacks (Gragg 2003).

Policies

Security policies are the foundation of a successful defense strategy. In addition to a generic security policy, specific ones may be advisable, such as remote access. Employees are required to take note of the policies by acknowledging in written form, usually together with

³¹ *Die Welt*, German newspaper. Article about the unbelievable story of Gert Postel, the trained postman posing as a senior psychiatrist: www.welt.de/data/1999/01/20/623409.html.

³² *Die Welt*, German newspaper: www.welt.de.

signing their contract. Updates and enhancements have to be propagated in a correct manner so no one is missed.

In order to generate a sound security policy and before putting procedures into place, risk identification and assessment must take place, which consists roughly of the following steps³³:

1. Identification of assets
2. Identification of risks/threats
3. Risk analysis—analysis of potential impact of the risks to the organization
4. Prioritization of risks
5. Planning and establishment of controls for risk mitigation
6. Monitoring

Policies have to target certain areas in order to provide a defense against social engineering—for example, they should address information-access controls, establishment and termination of accounts, management and approval of access rights, and password changes and complexity. However, physical security details such as locks, IDs, paper shredding (discussed in the section on “Dumpster Diving,” above), and escorting of visitors need to be addressed. To decrease the chance of a dumpster-diving attack, for example, trash bins should be kept out of public access. People have to know how to respond to unusual requests. They should not be put in the situation of having to decide themselves whether information is allowed to be handed out (Gragg 2003).

Thus, a data-classification policy is of great importance as well. It helps to implement controls with respect to disclosing information (Mitnick and Simon 2003). Data not explicitly classified must retain a default state of confidential to minimize risk.

Security Awareness versus Technological Measures

Because social engineering targets the weakest link in the security chain of an organization—human beings—this is what countermeasures mainly have to focus on. People are simply unaware of the risks and dangers, which arise from security breaches like, for example, the leaking of classified or personal information. This is where the concept of *security awareness* emerges.

It is a widely accepted position that technological measures are of only very limited use against social engineering attacks. Even Gragg, in his *Multi-Level Defense against Social Engineering*, focuses only on policy and training issues (Gragg 2003).

The truth is that there is no technology in the world that can prevent a social engineering attack (Mitnick and Simon 2003).

In short: Do not rely only on security devices. To neutralize such hacker's techniques, one must use their own weapons against them: good old grey matter (Lafrance 2004).

Security awareness is the process of making people realize the importance of security and the consequences of security failure. Training on policies and procedures is important, but people will pay far more attention and will be far more likely to follow security policies if they know about the risks, which are targeted. Constant reminders and training make employees effective in identifying attacks and responding in an appropriate manner (Kratt 2005). That is why an ongoing awareness program is of great importance; some authorities recommend that 40% of a company's overall security budget be spent on security-awareness training (Mitnick and Simon 2003).

For example, it is a big problem that most people are not aware of the danger the exposure of personal information bears. “I’ve got nothing to hide” is a sentence one can hear quite often when asking people about freely available personal information about them. But each tiny bit of information can be abused for purposes of social engineering. A social engineer could call a target's neighbors to collect more information or even trick them to give away the key to the target's house they store for emergency cases. Names of family members and pets along with birth dates are often used as passwords, as surveys show (see section on “Password Problems,” above). In addition, all of the above-mentioned information can be used to impersonate the target.

The Computer Security Institute (CSI)³⁴ conducts a yearly “Computer Crime and Security Survey” with the participation of the San Francisco Federal Bureau of Investigation's (FBI)³⁵ Computer Intrusion Squad. The following figures are based on data published in the 2006 survey and illustrate the significance of security awareness. Though the survey emphasizes computer security, and the term *social engineering* is used only with respect to information technology, the importance of security awareness holds true for other areas as well.

Because social engineering targets the human being as the weakest link in information society, security-awareness training is a key point in developing a proper defense against social engineering. The figures below emphasize the importance of the concept of security-awareness training. They give an overview of the components of and show the status quo of the investments in security-awareness training. Finally, commonly used security technologies are viewed from a social-engineering point of view.

Figure 1 shows the importance of security-awareness training that the 599 responding computer security practitioners in U.S. corporations, government agencies, financial institutions, and medical institutions attribute to various areas of security. For seven of the eight areas, training was seen as very important. The results indicate an overall substantial increase in the perception of

³⁵ Home page of the Federal Bureau of Investigation (FBI): www.fbi.gov.

Figure 1: Importance of security-awareness training in specific areas (599 respondents) (Computer Security Institute 2006)

the importance of security-awareness training, compared to last year's result. Figure 1 shows the current figures (Computer Security Institute 2006).

Figure 2 gives a review of which organizations invest the most in security-awareness training. It is based on the replies of 483 respondents who were asked if their organization invested sufficiently in security-awareness training. The interesting result is that, "on average, respondents from 10 out of the 15 sectors do not believe that their organization invests enough in security awareness." The survey also presents numbers on the overall security operating expenditures and capital investment. In all but three sectors (federal government, utilities, and transportation), the perception that sufficient resources are being devoted to overall security and capital investment is much higher than security-awareness training. Thus, security-awareness training once more appears to

be a prime area for additional funding (Computer Security Institute 2006).

The alarming fact is that most security practitioners know about the lack of investment in security-awareness training in their organizations and no substantial improvement has taken place over the past two years. This is an important finding to remember when discussing social engineering. Security awareness is the most important countermeasure to social engineering; security practitioners know that their organization is not investing enough on security awareness; still, there is no improvement, because decision makers obviously do not recognize the threat. As a conclusion, this means the door to social-engineering attacks remains wide open.

Figure 3 illustrates which security technologies are most commonly used. Compared to last year, the results shown in Figure 3 are approximately the same, apart from newly introduced categories. The use of biometrics increased from 15% to 20% compared to last year's results. Although the reported use of encryption for data in transit and reusable account/log-in passwords went down, the use of intrusion-prevention systems (IPSs) increased. The difference between IPSs and firewalls is the divergent approach: while firewalls use a so-called whitelist approach by blocking all traffic except the one they have a reason to pass, IPSs pass all traffic unless they have a reason to block it (Computer Security Institute 2006).

It is easy to see that none of the top-listed technologies—neither firewalls nor antivirus software—are able to fend off a (nontechnical) social-engineering attack. This holds true for the other entries as well, since the "human factor" is neglected by purely technological measures. Security technology raises overall security, but neither cryptography nor passwords or biometrics can keep an employee from simply giving out proprietary information when deceived by a social engineer. Passwords as a

Figure 2: Responses of 483 security practitioners about whether their organization invests enough in security-awareness training (mean values reported on a seven-point scale) (Computer Security Institute 2006)

Figure 3: Security technologies used (616 respondents) (Computer Security Institute 2006)

special topic are discussed in the section on “Password Problems,” above.

The newly introduced category of antispyware software ranks third, though. Certain technical approaches that may be used by an attacker to gain information (e.g., the use of key loggers to get users’ passwords) may be tackled by technologies of this category, along with anti-virus software, which is ranked second.

The following conclusion may be drawn from the above-mentioned information: Figure 3 points out that most respondents participating invest considerably in security technologies. Figure 1 illustrates that the perception of the importance of security-awareness training has increased in the past year, compared with last year’s results, while Figure 2 shows that most security practitioners still sense a lack of investment in security-awareness training. As already stated, it is hardly possible to conquer social engineering using only technological measures. On the contrary, the findings show that organizations invest considerably in security technologies, while security practitioners sense a lack of security-awareness training, which most likely stems from decision makers’ lack of perception of the importance of this training. Thus, as a conclusion, management should be more aware of the possibility and dangers of attacks like social engineering in order to grant adequate funds for security-awareness training.

Training

Policies are worth only the paper they are printed on if they are not enforced. The most important concept in dealing with human beings as the weakest link in an organization’s security chain is education and training. An employee who is regularly required to attend

security-awareness trainings is far less likely to fall for social-engineering attacks, and the mere signing of a security policy does not make the person more security-aware.

Incident Response

The issue of incident response is closely linked to the topic of continuous training. If an employee has uncovered a social-engineering attack, there must be a defined process for how to deal with the situation. Incidents have to be communicated through the entire organization in a timely manner so that the attacker does not have the chance of just looking for another victim who is less security-aware. Incidents should be tracked in a centralized way by a responsible person or department (Gragg 2003).

Termination Process

An organizational measure against social engineering is the establishment of a well-functioning termination process. The termination process ensures that employees have their user accounts and access rights removed in a timely manner once they leave the organization. This is of prime importance, as attacks may be conducted by disgruntled former workers. In addition to the danger of former employees still having access to sensitive information, a social engineer could deliberately try to guess the credentials of laid-off personnel.

While workers are on vacation their accounts could be locked instead of deleted in order to provide a higher level of security (Jones 2004). Locking instead of deletion makes sure there is no distraction from work once employees return, as the accounts can easily be unlocked again.

Technological Countermeasures

Although technological measures alone are not sufficient to provide a defense against social-engineering attacks, as discussed above, they can at least complicate an attack. The following list provides some examples; we will not discuss this topic in detail.

- *Network security:* The network should be protected against “sniffing” to prohibit easy spying on the data. Switches, for example, provide higher security than hubs by sending traffic only to the concerned computer (“unicast”) rather than to all attached ones (“multicast”). However, this protection can be circumvented as well, for example with “arp spoof,” which is part of the *dsniff*¹⁸ package. A virtual private network (VPN) can add a layer of encryption in order to counter sniffing attacks. E-mails containing confidential information should be encrypted.
- *Virus scanners* provide a basic protection against malicious applications such as viruses, worms, and Trojan horses. They are available for different operating systems. There are also different types of virus scanners, which target servers, clients, and e-mail. Suspicious e-mail attachments can automatically be put in a vault and later released on request. Messages containing viruses can be deleted.

- *Intrusion-detection systems (IDS) and intrusion-prevention systems (IPS)*: Intrusion-detection systems detect unusual manipulations to systems by analyzing certain parameters like network traffic (network IDS) or logs and system calls (host-based IDS) for suspicious patterns. IDSs only issue warnings, whereas IPSs proactively respond to the assumed threat—for example by logging a user off (Rash et al. 2005). However, both systems must be finely adjusted in order to keep false positive results at a low level.
- *Media* containing confidential data must be handled suitably, which involves not only proper storage but also deletion processes. Data on magnetic storage media should be erased in a proper way, which includes wiping (overwriting data) or the use of degaussers.³⁶ Physical destruction like burning, grinding, or shredding should be considered for all media.

TESTING COUNTERMEASURES

Countermeasures and policies must be tested on an ongoing basis. They have to be maintained frequently; simulated attacks should be conducted regularly in order to find weak spots (Orgill et al. 2004, Allen 2001).

An interesting problem arises if employees are told that the level of security is satisfactory, as they may become complacent. Thus, both administration and employees will let their guard down. In fact, increased security measures even make psychological attacks easier because people think their data are safe (Dubin 2002). This always has to be kept in mind when testing countermeasures: negative findings may and will happen; however, they should not produce a bitter aftertaste. Instead, a communicated conclusion of “everything is great” may even lead to counterproductive results. Testing the compliance to the security policy and determining how vulnerable a company is to social engineering attacks is an important and complex topic. Hasle et al. (2005), for instance, propose a metric to measure the degree of vulnerability.

GUIDELINES

This section provides a brief set of guidelines (in random order) to identify and thus reduce the chance of a successful social-engineering attack.

- Follow the security policy; by doing so, no one will be able to accuse you of doing something wrong. Do not make exceptions.
- Know your fellow employees. By doing so, it is easy to spot suspicious unescorted visitors.
- Allow yourself to be mistrustful. Although being mistrustful complicates the process of making new friends, it may protect both you and them from damage and thus help in keeping old friends.

- Do not reciprocate mindlessly. If strangers do you a favor and then ask for a favor in return, think twice about what they are asking for.
- Ask unpleasant questions. Do not be rude to strangers or fellow employees you do not know and who are requesting information from you, but do ask them to identify themselves clearly. Bogus questions are a great opportunity to identify attackers in an early stage; an example is provided by Gragg:

“Oh Mr. Smith, how is your daughter? Is she getting better from the accident?” If the caller says, “My daughter wasn’t in an accident.” or “I don’t have a daughter,” the caller has passed a single test. At this point the employee would apologize and explain that he or she must be mistaken. However, if the caller starts talking about the accident or lets the target talk about the accident, then the hacker has been hooked. (Gragg 2003)

- Take your time. Many social-engineering attacks work by applying some kind of pressure. Do not let an attacker fool you into revealing confidential information because of an “emergency case.” There always has to be the time to thoroughly check whether a request is justified and the acting persons are authorized.
- Complying with authority is good; verification of authority is better. Though supervisors may react in an offended way when being asked for identification, it is even more important to do so. By strictly following the security policy even when “superiors” or their “secretaries” ask for information you demonstrate your correct understanding and awareness concerning security.
- Report recognized or suspected social-engineering attacks immediately.

CONCLUSION

Social engineering is a kind of attack, which cannot be remedied by technological measures, as it targets the weakest link in an organization’s security chain, the human factor. You paradoxically fall for it because you believe in the good nature of human beings. It is a “soft” kind of attack and thus has to be countered by applying equivalent defense strategies. The most important step in doing so is to raise security awareness and keep it at a high level through continuous training, whereas purely technological countermeasures can be seen only as a supplement.

GLOSSARY

Dumpster Diving: The act of taking trash from dumpsters of an organization or individual in the hope of acquiring information.

Phishing: Most easily described as the practice of directing users to fraudulent Web sites.

Reciprocation: Most easily described as an automatic urge to respond to a gift or favor one receives.

Shoulder Surfing: Observation during password entry.

³⁶ Degaussers are able to completely erase all data from magnetic storage media, whereas overwriting does not erase all data. An example source for degaussers: www.veritysystems.com/degaussers/index.asp.

Social Proof: Instead of developing an opinion by themselves, people usually rely to a certain degree on what other people are doing or saying.

INTRODUCTION

Intuitively, *intrusions* in an information system are the activities that violate the security policy of the system, and *intrusion detection* is the process used to identify intrusions. Intrusion detection has been studied for over 20 years, since Anderson's (1980) report. It is based on the beliefs that an intruder's behavior will be noticeably different from that of a legitimate user and that many unauthorized actions will be detectable.

Intrusion-detection systems (IDSs) are usually deployed along with other preventive security mechanisms, such as access control and authentication, as a second line of defense that protects information systems. There are several reasons that make intrusion detection a necessary part of the entire defense system. First, many traditional systems and applications were developed without security in mind. In other cases, systems and applications were developed to work in a different environment and may become vulnerable when deployed in the current environment. (For example, a system may be perfectly secure when it is isolated but become vulnerable when it is connected to the Internet.) Intrusion detection provides a way to identify and thus allow responses to attacks against these systems. Second, because of the limitations of information security and software engineering practice, computer systems and applications may have design flaws or bugs that could be used by an intruder to attack the systems or applications. As a result, certain preventive mechanisms (e.g., firewalls) may not be as effective as expected.

Intrusion detection complements these protective mechanisms to improve system security. Even if the preventive security mechanisms can protect information systems successfully, it is still desirable to know what intrusions have happened or are happening, so that we can understand the security threats and risks and thus be better prepared for future attacks. Ideally, intrusion detection can be used as the foundation for reactive measures. For example, when a denial of service (DoS) attack

is detected, a firewall may be reconfigured to filter out the attack traffic. Moreover, intrusion detection can also be used to enforce accountability and compliance with security policy. This is particularly important to deal with threats from inside attackers, who are authorized to access the information system but may misuse their privileges to perform actions that violate the security policy.

In spite of their importance, IDSs are not replacements for preventive security mechanisms, such as access control and authentication. Indeed, IDSs themselves cannot provide sufficient protection for information systems. As an extreme example, if an attacker erases all the data in an information system, detecting the attacks cannot reduce the damage. Thus, IDSs should be deployed along with other preventive security mechanisms as a part of a comprehensive defense system.

Denning (1986) presented the first intrusion-detection model, which has six main components: subjects, objects, audit records, profiles, anomaly records, and activity rules. *Subjects* refer to the initiators of activity in an information system; they are usually normal users. *Objects* are the resources managed by the information system, such as files, commands, and devices. *Audit records* are those generated by the information system in response to actions performed or attempted by subjects on objects. Examples include user log-in, command execution, etc. *Profiles* are structures that characterize the behavior of subjects with respect to objectives in terms of statistical metrics and models of observed activity. *Anomaly records* are indications of abnormal behaviors when they are detected. Finally, *activity rules* specify actions to take when some conditions are satisfied, which update profiles, detect abnormal behaviors, relate anomalies to suspected intrusions, and produce reports.

Since Denning's (1986) model, intrusion-detection techniques have evolved into two classes: anomaly detection and misuse detection. *Anomaly detection* is based on the normal behavior of a subject (e.g., a user or a

system); any action that significantly deviates from the normal behavior is considered intrusive. Denning's intrusion-detection model is an example of anomaly detection. *Misuse detection* catches intrusions in terms of the characteristics of known attacks or system vulnerabilities; any action that conforms to the pattern of a known attack or vulnerability is considered intrusive. The rationale of misuse detection is that with additional knowledge of known attacks or vulnerabilities, we can potentially detect these attacks more precisely and more quickly.

Alternatively, IDSs may be classified into host-based IDSs, distributed IDSs, and network-based IDSs according to the sources of the audit information used by each IDS. Host-based IDSs get audit data from host audit trails and usually aim at detecting attacks against a single host; distributed IDSs gather audit data from multiple hosts, and possibly the network that connects the hosts, aiming at detecting attacks involving multiple hosts. Network-based IDSs use network traffic as the audit data source, relieving the burden on the hosts that provide normal computing services.

This chapter starts with an overview of current intrusion-detection techniques. Next, it reviews the various types of anomaly-detection methods, such as statistical models and machine learning methods, followed by an overview of misuse-detection methods, including rule-based languages, the colored Petri-net-based method, and the abstraction-based method. The section following that describes techniques for automatically generating attack signatures, including a data-mining framework for learning attack signatures and recent advances in the automatic generation of worm signatures. This chapter continues to discuss host-based IDSs as well as additional techniques for intrusion detection in distributed systems, including distributed IDSs, network-based IDSs, and interoperation between (heterogeneous) IDSs. Finally, this chapter reviews intrusion-alert correlation techniques.

ANOMALY DETECTION

Statistical Models

Statistical modeling is among the earliest methods used for detecting intrusions in electronic information systems. It is assumed that an intruder's behavior is noticeably different from that of a normal user, and statistical models are used to aggregate the user's behavior and distinguish an attacker from a normal user. The techniques are applicable to other subjects, such as user groups and programs. In some cases, a simple threshold value is used to indicate the distinction (as with the common rule of raising an alarm if the password is mistyped three times); alternatively, more complex statistical models may be used. Here, we discuss two statistical models that have been proposed for anomaly detection: NIDES/STAT and Haystack.

NIDES/STAT

The Stanford Research Institute's next-generation real-time intrusion-detection expert system statistical component (NIDES/STAT) observes behaviors of subjects on a monitored computer system and adaptively learns what is normal for individual subjects, such as users and groups

(Axelsson 1999). The observed behavior of a subject is flagged as a potential intrusion if it deviates significantly from the subject's expected behavior.

The expected behavior of a subject is stored in the subject's profile. Various measures are used to evaluate different aspects of a subject's behavior. When audit records are processed, the system periodically generates an overall statistic, T^2 , that reflects the abnormality of the subject. This value is a function of the abnormality values of all the measures comprising the profile. Suppose that n measures $M_1, M_2, \dots, M_n$ are used to model a subject's behavior. If $S_1, S_2, \dots, S_n$ represent the abnormality values of M_1 through M_n , then the overall statistic T^2 is evaluated as follows, assuming that the n measures are independent of each other:

$$T^2 = S_1^2 + S_2^2 + \dots + S_n^2.$$

The profile of a subject is updated to reflect the changes of the subject's behavior. To have the most recently observed behaviors influence the profile more strongly, NIDES/STAT multiplies the frequency table in each profile by an exponential decay factor before incorporating the new audit data. Thus, NIDES/STAT adaptively learns a subject's behavior patterns. This keeps human users from having to manually adjust the profiles; however, it also introduces the possibility of an attacker gradually "training" the profile to consider his/her intrusive activities as normal behavior.

Haystack

Haystack used a different statistical anomaly-detection algorithm, which was adopted as the core of the host monitor in the distributed intrusion-detection system (DIDS) (Axelsson 1999). This algorithm analyzes a user's activities according to a four-step process.

First, the algorithm generates a session vector to represent the activities of the user for a particular session. The session vector $\mathbf{X} = \langle x_1, x_2, \dots, x_n \rangle$ represents the counts for various attributes used to represent a user's activities for a single session. Examples of the attributes include session duration and number of files opened for reading.

Second, the algorithm generates a Bernoulli vector to represent the attributes that are out of range for a particular session. A threshold vector $\mathbf{T} = \langle t_1, t_2, \dots, t_n \rangle$, where t_i is a tuple of the form $\langle t_{i,\min}, t_{i,\max} \rangle$, is used to assist this step. The threshold vector is stored in a user's profile. The Bernoulli vector $\mathbf{B} = \langle b_1, b_2, \dots, b_n \rangle$ is generated so that b_i is set to 1 if x_i falls outside the range t_i , and b_i is set to 0 otherwise.

Third, the algorithm generates a weighted intrusion score, for a particular intrusion type, from the Bernoulli vector and a weighted intrusion vector. Each group and intrusion type pair has a weighted intrusion vector $\mathbf{W} = \langle w_1, w_2, \dots, w_n \rangle$, in which each w_i relates the importance of the i th attribute in the Bernoulli vector to detecting the particular intrusion type. The weight intrusion score is simply the sum of all weights, w_i , where the i th attribute falls outside the range t_i . That is,

$$\text{the weighted intrusion score} = \sum_{i=1}^n b_i \cdot w_i.$$

Finally, the algorithm generates a suspicion quotient to represent how suspicious this session is compared with all other sessions for a particular intrusion type. Specifically, the suspicion quotient is the probability that a random session's weighted intrusion score is less than or equal to the weighted intrusion score computed in the previous step.

Unlike NIDES/STAT, the Haystack algorithm has a step that determines resemblance to known attacks. The advantages are that more knowledge about the possible attacks can be derived from this step and better responses can follow the alarms. However, extra knowledge about possible intrusion types is required: We need to understand the impact of the intrusion types on the attributes of the session vectors and assign appropriate weights to these attributes to reflect the impact. In reality, the process of generating the weighted intrusion vectors is time consuming and error prone.

Machine-Learning and Data-Mining Techniques

A number of machine-learning and data-mining techniques have been investigated for the purpose of anomaly detection. The focus of these approaches is to "learn" the normal behaviors of the system automatically from the historic normal data. Such normal behaviors are represented in various forms and used as the basis for future anomaly detection. More of these approaches use "unsupervised" learning—that is, training anomaly detectors without requiring the training data be labeled. (By contrast, a supervised learning approach requires that each training data entry be labeled as normal or intrusive (or as a specific intrusion). In this section, we discuss several approaches in this category.

Time-Based Inductive Machine

Teng, Chen, and Lu (1990) proposed the use of a time-based inductive machine (TIM) to capture a user's behavior pattern. As a general-purpose tool, TIM discovers temporal sequential patterns in a sequence of events. The sequential patterns represent highly repetitive activities and are expected to provide predication. The temporal patterns, which are represented in the form of rules, are generated and modified from the input data using a logical inference called "inductive generalization." When applied to intrusion detection, the rules describe the behavior patterns of either a user or a group of users based on past audit history. Each rule describes a sequential event pattern that predicts the next event from a given sequence of events. An example of a simplified rule produced in TIM is

$$E1 - E2 - E3 \rightarrow (E4 = 95\%; E5 = 5\%),$$

where $E1$, $E2$, $E3$, $E4$, and $E5$ are security events.

This rule says that if $E1$ is followed by $E2$, and $E2$ is followed by $E3$, then there is a 95% chance (based on the previous observation) that $E4$ will follow, and a 5% chance that $E5$ will follow. TIM can produce more

generalized rules than the above. For example, it may produce a rule in the form

$$E1 - * \rightarrow (E2 = 100\%),$$

where an asterisk matches any single event. Any number of asterisks is allowed in a rule.

The limitation of TIM is that it considers only the immediately following relationship between the observed events. That is, the rules represent only the event patterns in which events are adjacent to each other. However, a user may perform multiple tasks at the same time. For example, a user may check his/her e-mail during the editing of a document. The events involved in one application, which tend to have strong patterns embedded in the sequence of events, may be interleaved with events from other applications. As a result, it is very possible that the rules generated by TIM cannot precisely capture the user's behavior pattern. Nevertheless, TIM may be suitable for capturing the behavior patterns of entities such as programs that usually focus on single tasks.

Instance-Based Learning

Lane and Brodley (1998) applied instance-based learning (IBL) to learn entities' (e.g., users) normal behavior from temporal sequence data. IBL represents a concept of interest with a set of instances that exemplify the concept. The set of instances is called the "instance dictionary." A new instance is classified according to its relation to stored instances. IBL requires a notion of "distance" between the instances so that the similarity of different instances can be measured and used to classify the instances.

Lane and Brodley did several things to adapt IBL to anomaly detection. First, they transformed the observed sequential data into fixed-length vectors (called "feature vectors"). Specifically, they segmented a sequence of events (e.g., a sequence of user commands) into all possible overlapping sequences of length l , where l is an empirical parameter. (Thus, each event is considered the starting point of a feature vector, and each event is replicated l times.) Second, they defined a similarity measure between the feature vectors. For a length l , the similarity between feature vectors $\mathbf{X} = (x_0, x_1, \dots, x_{l-1})$ and $\mathbf{Y} = (y_0, y_1, \dots, y_{l-1})$ is defined by the functions

$$w(X, Y, i) = \begin{cases} 0 & \text{if } i < 0 \text{ or } x_i \neq y_i \\ 1 + w(X, Y, i-1), & \text{if } x_i = y_i \end{cases}$$

and

$$\text{Sim}(X, Y) = \sum_{i=0}^{l-1} w(X, Y, i).$$

The converse measure, distance, is defined as $\text{Dist}(\mathbf{X}, \mathbf{Y}) = \text{Sim}_{\max} - \text{Sim}(\mathbf{X}, \mathbf{Y})$, where $\text{Sim}_{\max} = \text{Sim}(\mathbf{X}, \mathbf{X})$. Intuitively, the function $w(\mathbf{X}, \mathbf{Y}, i)$ accumulates weights from the most recently consecutively matched subsequences between $\mathbf{X}$ and $\mathbf{Y}$ at position i , whereas $\text{Sim}(\mathbf{X}, \mathbf{Y})$ is the integral of total weights.

A user profile is built to contain a collection of sequences, D , selected from a user's observed actions (e.g., commands). The similarity between the profile and a newly observed sequence, X , is defined as $Sim_D(X) = \max_{Y \in D} [Sim(Y, X)]$. That is, the similarity between X and D is defined as the similarity between X and a vector in D that is most similar to X . Then a threshold r is chosen. If the similarity between an observed sequence X and the profile D is greater than r , X is considered normal; otherwise, X is abnormal.

To reduce the storage required by the profile, Lane and Brodley used the least-recently-used pruning strategy to keep the profile at a manageable size. As new instances are acquired and classification is performed, the profile instance selected as most similar is time stamped. Least-recently-used instances are removed when the profile is constrained to the desired size. In addition, they applied a clustering technique to group the instances in the profile, and they used a representative instance for each cluster.

This attempt shares a problem similar to that of TIM—that is, it tries to find patterns from sequences of consecutive events. As the authors have noted, a user may interrupt his/her normal work (e.g., programming) and do something different (e.g., answer an urgent e-mail) and thus yield a different sequence of actions from his/her profile. Lane and Brodley's (1998) solution is to use a time average of the similarity signals; however, such a solution may make real anomalies unnoticeable. In addition, the least-recently-used pruning strategy gives an attacker a chance to train the profile slowly, so that intrusive activities are considered normal ones.

Neural Network

Fox et al. (1990) were the first to attempt modeling system and user behaviors using neural networks. Their choice of neural network is Kohonen's (1982) self-organizing map (SOM), which is a type of unsupervised learning technique that can discover underlying structures of the data without prior examples of intrusive and nonintrusive activities.

They used SOM as a real-time background monitor that alerts a more complex expert system. In their prototype system, eleven system parameters accessible from the system's statistical performance data are identified as the input to the SOM model. These parameters include: (a) central processing unit (CPU) usage, (b) paging activity, (c) mailer activity, (d) disk accesses, (e) memory usage, (f) average session time, (g) number of users, (h) absentee jobs, (i) reads of "help" files, (j) failed log-ins, and (k) multiple log-ins. However, their study showed the results of only one simulated virus attack, which is not sufficient to draw serious conclusions.

In another attempt to apply neural network to anomaly detection, Ghosh, Wanken, and Charron (1998) proposed using a back-propagation network to monitor running programs. A back-propagation network is developed for supervised learning. That is, it needs examples of intrusive and nonintrusive activities (called "training data") to build the intrusion-detection model. Such a network consists of an input layer, at least one hidden layer (neurons that are not directly connected to the input or output nodes), and an output layer. Typically, there are no

connections between neurons in the same layer or between those in one layer and those in a previous layer.

The training cycle of a back-propagation network works in two phases. In the first phase, the input is submitted to the network and propagated to the output through the network. In the second phase, the desired output is compared with the network's output. If the vectors do not agree, the network updates the weights starting at the output neurons. Then the changes in weights are calculated for the previous layer and cascade through the layers of neurons toward the input neurons.

Ghosh et al. proposed using program input and the program internal state as the input to the back-propagation network. One interesting result is that they improved the performance of detection by using randomly generated data as anomalous input. By considering randomly generated data as anomalous, the network gets more training data that is complementary to the actual training data.

Similarly to statistical anomaly detection models, deciding the input parameters for neural network anomaly detectors is a difficult problem. In addition, assigning the initial weights to the neural networks is also an unresolved question. The experiments by Ghosh et al. (1998) showed that different initial weights could lead to anomaly detectors with different performance. Nevertheless, research on applying neural networks to anomaly detection is still preliminary; more work is needed to explore the capability of neural networks.

Audit Data Analysis and Mining

Audit data analysis and mining (ADAM) proposes applying data-mining techniques to discover abnormal patterns in large amounts of audit data (e.g., network traffic collected by TCPdump, which is a program used to sniff and store packets transmitted in the network) (Barbara et al. 2001, 2002). (Lee and Stolfo [2000] use data-mining techniques for automatically generating misuse models; we will discuss it in the section on "Misuse Detection" later in this chapter.) In particular, the existing research focuses on the analysis of network audit data, such as the transmission control protocol (TCP) connections. Using data-mining techniques, ADAM has the potential to provide a flexible representation of the network traffic pattern, uncover some unknown patterns of attacks that cannot be detected by other techniques, and accommodate the large amount of network audit data that keeps growing in size.

ADAM uses several data-mining-related techniques to help detect abnormal network activities. The first technique ADAM uses is inspired by association rules. Given a set I of items, an association rule is a rule of the form $X \rightarrow Y$, where X and Y are subsets (called item sets) of I and $X \cap Y = \emptyset$. Association rules are usually discovered from a set T of transactions, where each transaction is a subset of I . The rule $X \rightarrow Y$ has a *support* s in the transaction set T if $s\%$ of the transactions in T contain $X \cup Y$, and it has a *confidence* c if $c\%$ of the transactions in T that contain X also contain Y .

However, ADAM does not use association rules directly; instead, it adopts the item sets that have large enough support (called "large item sets") to represent the pattern of network traffic. Specifically, it assumes that each network event (e.g., a TCP connection) is described

by a set of attribute values and considers each event a transaction. The large item sets discovered from the network traffic then represent the frequent events in the network traffic. The power of such a mechanism lies in the flexible representation of events.

ADAM builds a profile of normal network activities in which the frequent events (represented by large item sets) are stored. During the detection time, it adopts a sliding-window method to incrementally examine the network events. Within each window, ADAM looks for the large item sets that do not appear in the profile and considers them suspicious.

The second technique ADAM uses is called “domain-level mining.” Intuitively, it tries to generalize the event attribute values used to describe a network event. For example, an IP address that belongs to the subnet *ise.gmu.edu* can be generalized to *ise.gmu.edu*, *gmu.edu*, and *edu*. Then it discovers large item sets using the generalized attribute values. An advantage of this approach is that it provides a way to aggregate the events that have some commonality and may discover more attacks. However, the scheme used to generalize the attribute values is ad hoc; only generalization from IP addresses to subnets and from smaller subnets to larger subnets are studied.

The third technique ADAM uses is classification. ADAM is innovative in that classification is used to classify the output of the mining of large item sets. Four classification algorithms have been studied to date: C4.5 decision tree, naive Bayes, cascading classifier (which uses decision tree followed by naive Bayes and vice versa), and inductive rule learner. The results show that classification is quite effective in reducing false alarms.

Finally, ADAM uses the pseudo-Bayes estimator to accommodate unknown attacks. It is assumed that unknown attacks are those that have not been observed. The training data are represented as a set of vectors, each of which corresponds to an event and is labeled as normal or as a known class of attacks. An additional class is then considered to represent the unknown attacks. Because the unknown attacks have not been observed in the training data, the probability $P(x|\text{class} = \text{unknown})$, where x is a training vector, is zero. The pseudo-Bayes estimator is used to smooth all the conditional probabilities $P(x|\text{class})$ so that $P(x|\text{class} = \text{unknown})$ is assigned a (small) probability. These conditional probabilities are then used to build a naive Bayes classifier.

The limitation of ADAM is that it cannot detect stealthy attacks. In other words, it can detect an attack only when it involves a relatively large number of events during a short period of time. This limitation occurs because ADAM raises an alarm only when the support of an unexpected rule (i.e., association of event attributes) exceeds a threshold. Indeed, this limitation is not unique to ADAM; most of the anomaly-detection models and many of the misuse-detection models suffer from the same problem.

Computer Immunological Approach

The computer immunological approach is based on an analogy of the immune system’s capability of distinguishing self from non-self (Hofmeyr, Forrest, and Somayaji 1998). This approach represents self as a collection of

strings of length l , where l is a systemwide parameter. A string of length l is considered non-self if it does not match any string belonging to self. To generate detectors that can distinguish non-self from self, a naive approach is to randomly generate a string of length l and check whether it matches any self-string. If yes, the generated string is discarded; otherwise, it is used as a detector. However, the naive approach takes time exponential to the number of self-strings. To address this problem, Forrest et al. proposed an “ r -contiguous-bits” matching rule to distinguish self from non-self: two l -bit strings match each other if they are identical in at least r contiguous positions. As a result, detectors can be generated more efficiently for this particular matching rule.

Hofmeyr et al. proposed using short sequences of system calls to distinguish self from non-self for anomaly detection. Given a program in a particular installation, the immunological approach collects a database of all unique system call sequences of a certain length made by the program over a period of normal operation. During the detection time, it monitors the system call sequences and compares them with the sequences in the aforementioned database. For an observed sequence of system calls, this approach extracts all sub-sequences of length l and computes the distance $d_{\min}(i)$ between each sub-sequence i and the normal database as $d_{\min}(i) = \min[d(i, j)]$ for all sequences j in the normal database, where $d(i, j)$ is the Hamming distance between sequences i and j (i.e., the number of different bits in sequences i and j). The anomaly score of the observed sequence of system calls is then the maximum $d_{\min}(i)$ normalized by dividing the length of the sequence. This approach raises an alarm if the anomaly score is above a certain threshold.

The advantage of this approach is that it has a high probability of detecting anomalies using a small set of self-strings based on short sequences of system calls. In addition, it does not require any prior knowledge about attacks. The disadvantage is that it requires self to be well understood. That is, it requires a complete set of self-strings in order not to mistake self for non-self. This requirement may be trivial for applications such as virus detection, but it is very difficult for intrusion detection, for which some normal behaviors cannot be foreseen when the detectors are being generated.

Sekar et al. 2001 further improve the computer immunological method by using an automaton to represent a program’s normal behavior. The program counter is used as the state of the automaton, and the system calls made by the program are used as the events that cause the state transitions. As a result, the automaton representation can accommodate more information about the programs’ normal behavior and, thus, reduce the false-alert rate and improve the detection rate. In addition, the automaton representation is more compact than the previous alternative. Consequently, such automata are easier to build and more efficient to use for intrusion detection.

The research on the computer immunological method has led to the development of an anomaly-detection system called STIDE (sequence time-delay embedding). People have independently and consistently found that a sequence length of six makes STIDE capable of detecting anomalies. Tan and Maxion (2002) investigated this problem by

establishing a framework of three sequence types: rare, common, and foreign. A rare (or common) sequence is one that occurs infrequently (or frequently) in the training data that defines the normal behavior. A foreign sequence is one that never occurs in the training data. A minimal foreign sequence is a foreign sequence having the property that all of its proper subsequences already exist in the training data. Tan and Maxion discovered that STIDE requires a sequence length of at least six because in all the data traces used for evaluating STIDE the length of the smallest minimal foreign sequence is six.

Specification-Based Methods

Ko, Ruschitzka, and Levitt (1997) proposed a specification-based approach for intrusion detection. The idea is to use *traces*, ordered sequences of execution events, to specify the intended behaviors of concurrent programs in distributed system. A specification describes valid operation sequences of the execution of one or more programs, collectively called a “(monitored) subject.” A sequence of operations performed by the subject that does not conform to the specification is considered a security violation. Each specification is called a “trace policy.” A grammar called “parallel environment grammars” (PE-grammars) was developed for specifying trace policies.

The advantage of this approach is that in theory, it should be able to detect some types of attacks that intruders will invent in the future. In particular, if a new attack causes a program to behave in a way outside the specification, then it will be flagged as a potential attack. The drawback of this approach is that substantial work is required to specify accurately the behavior of the many privileged system programs, and these specifications will be operating-system-specific. To address this issue, Ko (2000) proposed the use of *inductive logic programming* to synthesize specifications from valid traces. The automatically generated specifications may be combined with manual rules to reduce the work involved in specification of valid program behaviors.

Wagner and Dean (2001) further advanced the specification-based approach. The basic idea is to automatically generate the specification of a program by deriving an abstract model of the programs from the source or binary code. Wagner and Dean studied several alternative models, including the call-graph model and the abstract-stack model. Central to these models is the control flow graph of a program; these models adopt different ways to represent the possible system call traces according to the control flow graph. Attractive features of this approach are that it has the potential to detect unknown patterns of attacks and that it has no false alerts, although it may miss some attacks. Moreover, the specification-based methods also offer an opportunity to stop ongoing attacks. For example, it is possible to automatically embed code (e.g., embedded sensors by Zamboni [2001]) into an existing program, which forces the program to quit when certain specifications are violated.

Information-Theoretic Measures

Lee and Xiang (2001) proposed the use of information-theoretic measures to help understand the characteristics

of audit data and build anomaly-detection models. The well-known concept of *entropy* is the first information-theoretic measure. Given a set of classes C_X and a data set X , where each data item belongs to a class $x \in C_X$, the entropy of X relative to C_X is defined as

$$H(X) = \sum_{x \in C_X} P(x) \log \frac{1}{P(x)},$$

where $P(x)$ is the probability of x in X . For anomaly detection, entropy reveals the regularity of audit data with respect to some given classes.

The second information-theoretic measure is *conditional entropy*. The conditional entropy of X given Y is the entropy of the probability distribution $P(x|y)$; that is,

$$H(X/Y) = \sum_{x,y \in C_X, C_Y} P(x,y) \log \frac{1}{P(x|y)},$$

where $P(x,y)$ is the joint probability of x and y and $P(x|y)$ is the conditional probability of x given y . The conditional entropy is proposed to measure the temporal or sequential characteristics of audit data. Let X be a collection of sequences in which each is a sequence of n audit events and Y is the collection of prefixes of the sequences in X that are of length k . Then $H(X|Y)$ indicates the uncertainty that remains for the rest of the audit events in a sequence x after we have seen the first k events of x . For anomaly detection, conditional entropy can be used as a measure of regularity of sequential dependencies.

The limitation of conditional entropy is that it measures only the sequential regularity of contiguous events. For example, a program may generate highly regular sequences of events; however, if these events are interleaved with other sequences of events, the conditional entropy will be very high, failing to reflect the regularity embedded in the interleaved sequences.

The third information-theoretic measure, *relative entropy*, measures the distance of the regularities between two data sets. The relative entropy between two probability distributions $p(x)$ and $q(x)$ that are defined over the same $x \in C_X$ is

$$\text{relEntropy}(p|q) = \sum_{x \in C_X} p(x) \log \frac{p(x)}{q(x)}.$$

The fourth information-theoretic measure, *relative conditional entropy*, measures the distance of the regularities with respect to the sequential dependency between two data sets. The relative entropy between two probability distributions $p(x|y)$ and $q(x|y)$ that are defined over the same $x \in C_X$ and $y \in C_Y$ is

$$\text{relCondEntropy}(p|q) = \sum_{x,y \in C_X, C_Y} p(x,y) \log \frac{p(x|y)}{q(x|y)}.$$

Viewing intrusion detection as a classification problem, Lee and Xiang proposed the fifth information-theoretic measure, *information gain*, to measure the performance

of using some features for classification. The information gain of attribute (i.e., feature) A on data set X is

$$\text{Gain}(X, A) = H(X) - \sum_{v \in \text{Values}(A)} \frac{|X_v|}{|X|} H(X_v),$$

where $\text{Values}(A)$ is the set of values of A and X_v is the subset of X where A has value v . This measure can help choose the right features (i.e., the features that have high information gain) to build intrusion-detection models. The limitation of information gain is that it requires a relatively complete data set to help choose the right features for the classification model. Nevertheless, an intrusion-detection model cannot be better than the data set from which it is built.

Limitation of Anomaly Detection

Although anomaly detection can accommodate unknown patterns of attacks, it also suffers from several limitations. A common problem of all anomaly-detection approaches, with the exception of the specification-based approach, is that the subject's normal behavior is modeled on the basis of the (audit) data collected over a period of normal operation. If undiscovered intrusive activities occur during this period, they will be considered normal activities. A relevant issue is the progression of anomaly-detection models. Because a subject's normal behavior may change over time (for example, a user's behavior may change when he moves from one project to another), the IDSs that use some of the above approaches may allow the subject's profile to change gradually. This may give an intruder the chance to gradually train the IDS and trick it into accepting intrusive activities as normal. Thus, any profile change in an anomaly-detection system must be carefully performed to avoid such problems. Also, because these approaches are all based on summarized information, they are insensitive to stealthy attacks. The specification-based approaches do not suffer from the problems in training datasets. However, they may also have problems due to mistakes in (manual) specifications, and in some cases, it is difficult to develop specifications that precisely characterize the normal behaviors. Finally, because of some technical reasons, most of the current anomaly-detection approaches suffer from a high false-alarm rate.

Another difficult problem in building anomaly-detection models is how to decide the features to be used as the input of the models (e.g., the statistical models). In the existing models, the input parameters are usually decided by domain experts (e.g., network security experts) in ad hoc ways. It is not guaranteed that all and only the features related to intrusion detection will be selected as input parameters. Although missing important intrusion-related features makes it difficult to distinguish attacks from normal activities, having non-intrusion-related features could introduce "noise" into the models and thus affect the detection performance.

MISUSE DETECTION

Misuse detection is considered complementary to anomaly detection. The rationale is that known attack patterns

can be detected more effectively and efficiently by using explicit knowledge of them. Thus, misuse-detection systems look for well-defined patterns of known attacks or vulnerabilities; they can catch an intrusive activity even if it is so negligible that the anomaly-detection approaches tend to ignore it. Commercial systems often combine both misuse- and anomaly-detection approaches.

The major problems in misuse detection are the representation of known attack patterns and the difficulty of detecting new attacks. Another problem is an inherent limitation of misuse detection: While misuse-detection algorithms may sometimes detect variations of known attacks, they cannot identify truly new attacks since no pattern may be provided for them. Existing work on misuse detection is mostly aimed at the first problem, the representation of known attacks. The detection algorithms usually follow directly from the representation mechanisms. In this section, we discuss the typical ways to represent attacks.

Rule-Based Languages

The rule-based expert system is the most widely used approach for misuse detection. The patterns of known attacks are specified as rule sets, and a forward-chaining expert system is usually used to look for signs of intrusions. Here we discuss two rule-based languages, rule-based sequence evaluation language (RUSSEL) (Mounji et al. 1995) and production-based expert system tool set (P-BEST) (Lindqvist and Porras 1999). Other rule-based languages exist, but they are all similar in the sense that they all specify known attack patterns as event patterns.

RUSSEL

RUSSEL is the language used in the advanced security audit trail analysis on UNIX (ASAX) project (Mounji et al. 1995). It is a language specifically tailored to the problem of searching arbitrary patterns of records in sequential files. The language provides common control structures, such as conditional, repetitive, and compound actions. Primitive actions include assignment, external routine call, and rule triggering. A RUSSEL program simply consists of a set of rule declarations that are made of a rule name, a list of formal parameters and local variables, and an action part. RUSSEL also supports modules sharing global variables and exported rule declarations.

When intrusion detection is being enforced, the system analyzes the audit records one by one. For each audit record, the system executes all the active rules. The execution of an active rule may trigger (activate) new rules, raise alarms, write report messages, or alter global variables, for example. A rule can be triggered to be active for the current or the next record. In general, a rule is active for the current record because a prefix of a particular sequence of audit records has been detected. When all the rules active for the current record have been executed, the next record is read and the rules triggered for it in the previous step are executed in turn. User-defined and built-in C-routines can be called from a rule body.

RUSSEL is quite flexible in describing sequential event patterns and corresponding actions. The ability to work with user-defined C-routines gives the users the

power to describe almost anything that can be specified in a programming language. The disadvantage is that it is a low-level language. Specifying an attack pattern is similar to writing a program, although it provides a general condition-trigger framework and is declarative in nature. The feature that rules can share global variables introduces the possibility of bugs along with the convenience of sharing information among different rules.

P-Best

P-BEST was developed for the multiplexed information and computing service (Multics) intrusion-detection and alerting system (MIDAS) and later used by the intrusion-detection expert system (IDES), NIDES, and the event monitoring enabling responses to anomalous live disturbances (EMERALD) (Lindqvist and Porras 1999). The P-BEST toolset consists of a rule translator, a library of run-time routines, and a set of garbage-collection routines. Rules and facts in P-BEST are written in production-rule specification language. The rule translator is then used to translate the specification into an expert system program in C language, which can then be compiled into either a stand-alone, self-contained executable program or a set of library routines that can be linked to a larger software framework.

The P-BEST language is quite small and intuitive. In P-BEST, the user specifies the structure of a fact (e.g., an audit record) through a template definition referred to as a *pattern type*. For example, an event consisting of four fields—*event_type* (an integer), *return_code* (an integer), *username* (a string), and *hostname* (a string)—can be defined as `ptype[event_type: int, return_code: int, username: string, hostname: string]`.

Thus, P-BEST does not depend on the structure of the input data. One important advantage of P-BEST is that it is a language preprocessor (i.e., it generates a precompiled expert system) and can extend its ability by invoking external C functions. However, it shares a similar problem with RUSSEL: It is a low-level language. Specification of attack patterns in P-BEST is time consuming. When many related rules are included in a system, correctness of the rules is difficult to check due to the interaction of these rules.

State-Transition Analysis Toolkit

Though rule-based languages are flexible and expressive in describing attack patterns for misuse detection, in practice, they are usually difficult to use. As observed in Ilgun, Kemmerer, and Porras (1995), “in general, expert rule-bases tend to be non-intuitive, requiring the skills of experienced rule-base programmers to update them.” STAT was developed to address this problem.

In STAT, state-transition analysis technique was adopted to facilitate the specification of the patterns of known attacks (Ilgun et al. 1995). It is based on the assumption that all penetrations share two common features. First, penetrations require the attacker to possess some minimum prerequisite access to the target system. Second, all penetrations lead to the acquisition of some ability that the attacker does not have prior to the attacks. Thus, STAT views an attack as a sequence of actions performed by an

attacker that leads from some initial state on a system to a target-compromised state, where a *state* is a snapshot of the system representing the values of all memory locations on the system. Accordingly, STAT models attack as a series of state changes that lead from an initial secure state to a target-compromised state.

To represent attacks, STAT requires some critical actions to be identified. These *signature actions* refer to the actions that, if omitted from the execution of an attack scenario, would prevent the attack from successful completion. With the series of state changes and the signature actions that cause the state changes, an attack scenario is then represented as a state-transition diagram, where the states in the diagram are specified by assertions of certain conditions and the signature actions are events observable from, for example, audit data.
